12  cp.post(sum(i in R) s[i,n-i+1] == T);
13  cp.post(alldifferent(all(i in R,j in R) s[i,j]));
14 } using {
15   var<CP>{int} []vars = all(i in R,j in R) s[i,j];
16   while (!bound(vars)) {
17     selectMin[2](i in vars.getRange(): !vars[i].bound())(vars[i].getMin()) {
18       int mid = (vars[i].getMin()+vars[i].getMax()) / 2;
19       try<cp> cp.post(vars[i]<=mid); | cp.post(vars[i]>mid);
20     }
21   }
22 } onRestart cp.setRestartFailureLimit(cp.getRestartFailureLimit() + 100);

```

Figure 6. Restarting magic square.

[61–63], and Perron *et al.* [64] investigated how to define large neighborhoods based on the amount of propagations from constraints.

LNS differs from plain restarts by leaving a subset of the variables fixed so that the subsequent tree search solely focuses on the nonfixed variables. At each restart, a

different subset is fixed. Naturally, LNS is particularly useful in an optimization problem where a stream of solutions of increasing quality is desired. Indeed, one must have a solution handy when restarting to fix a subset of the variables to some value. The fragment

```

1  ...// the search
2 } onRestart {
3   Solution s = m.getSolution();
4   if (s!=null) {
5     forall(i in R)
6       if (lms.get() < 80) cp.post(x[i] == x[i].getSnapshot(s));
7   }
8 }
```

is a schematic LNS procedure. When the search restarts, it first retrieves the incumbent solution in line 3. If there is one, it

loops over all the variables and with an 80% chance, it constraints the *i*th variable to be equal to its value in the incumbent. Clearly,

```

1  int nbOrders = sz; range Orders = 1..nbOrders;
2  int nbSlabs = nbOrders; range Slabs = 1..nbSlabs;
3  set{int} colorOrders[c in Colors] = filter(o in Orders) (color[o] == c);
4  int maxCap = max(i in Caps) capacities[i];
5  int loss[c in 0..maxCap]=min(i in Caps: capacities[i] >= c) capacities[i] - c;
6  UniformDistribution dist(1..100);
7  Solver<CP> m();
8  var<CP>{int} x[Orders](m,Slabs);
9  var<CP>{int} l[Slabs](m,0..maxCap);
10
11 m.lnsOnFailure(4000);
12 minimize<m> sum(s in Slabs)loss[l[s]]
13 subject to {
14   m.post(multiknapsack(x,weight,l));
15   forall(s in Slabs)
16     m.post(sum(c in Colors) (or(o in colorOrders[c]) (x[o] == s)) <= 2);
17 } using {
18   forall(i in Orders)
19     tryall<m>(v in x[i].getMin()..x[i].getMax() : x[i].memberOf(v))
20       m.post(x[i] == v);
21   cout << x << endl;
22 } onRestart {
23   Solution s = CP.getSolution();
24   if (s != null) {
25     tryall<m>(i in 1..1000) {
26       forall(o in Orders)
27         if (dist.get() <= 90-10*i)
28           m.post(x[o] == x[o].getSnapshot(s));
29     }
30     m.setPrimalBound(s.getObjectiveValue());
31   }
32 }
```

Figure 7. The steel mill slab problem with large neighborhood search.

the subsequent search only focuses on the nonfixed variables.

Figure 7 illustrates the steel mill slab model of Refalo [65], which offered the first efficient CP model for this problem. It uses a LNS based on the above schema. The first change appears on-line 11 where the method call `m.lnsOnFailure(4000)`; imposes a limit of 4000 failures between two LNS restarts. The second change spans lines 23–32. It specifies which part of the solution to restore at the onset of an LNS round. It simply attempts (up to a thousand times) to fix some of the variable (randomly selected) to their value in the current solution. Line 30 also requires that the objective function improve. Naturally, the randomly selected subset of fixed variables may be inconsistent with the requirement to improve on the objective, in which case COMET will backtrack and consider another subset.

CONCLUSION

Search in CP is an integral part of the development of a solution to a problem. It provides ample opportunities to exploit the structure of the problem and steer the exploration process toward promising parts of the search space. It has traditionally been supported by languages offering a rich level of control. Search is best captured in terms of the specification of a search tree and its exploration strategy. While heuristics control the topology of the search tree and attempt to place promising nodes on the far left edge of the tree, strategies are mediators that compensate for the weaknesses of heuristics. Even though CP search is most often a complete procedure, meta-strategies deliver incomplete search techniques that are capable of tackling larger instances and taking advantage of randomization.

INTERDICTION BASICS

Network models are prevalent in operations research practice and theory because of their wide applicability to real-world problems. Nodes often represent junctions, connections, or facilities in a network, while arcs that connect these nodes may represent roadways, pipelines, cables, or virtual communication channels. One can model a broad array of scenarios using these concepts. A network may represent a physical entity such as a traffic grid, logistics transportation network, or telecommunication network, or logical entities such as project management schedules or production and inventory decisions.

In order to capture salient features of these networks, several properties are typically assigned to arcs and nodes in a network. The cost of an arc refers to the per-unit charge assessed for flows traversing the arc. In simultaneous flow networks (which are most common in network analysis), there are often flow capacities that restrict the amount of flow traversing the arc. Most flow networks also have supplies and demands associated with each node. Additionally, in many network design models, there are fixed costs for establishing nodes at certain places in the network, and for establishing arcs through which flows may be transmitted.

Given these foundations, it is indeed possible to model a wide array of practical optimization problems. However, these models often assume that data is known with certainty, and that all components of the network operate as intended. Furthermore, optimization models that design networks necessarily do so with limited

redundancy, since costs associated with capital development (e.g., roadways, transmission cables, and facilities) are typically minimized. Therefore, such networks are particularly vulnerable to disruptions such as arc failures.

The goal of network interdiction studies is to assess the vulnerability of networks to various types of failures (see Ref. 1 for an excellent introduction to this field). Most models of this type are Stackelberg games: a *leader* acts first and performs some interdiction actions on the network, and a *follower* responds by performing recourse operations on the network. Since the order and number of actions can vary depending on the model, we refer to these agents as the *interdictor* and *operator*, respectively, in this article, as is often done in the literature. Interdiction models typically have a single objective function on the part of the operator, and a limited disruption budget for the interdictor; this budget may, for example, refer to the number of arcs that can be eliminated in an interdiction act. Information is perfectly known to both agents, and the interdictor's objective is to hinder the operator's objective to the greatest extent possible.

For instance, consider a telecommunication network on which long-distance charges are incurred by routing calls between nodes on the network. Each arc represents a connection between points, and the per-unit flow costs on these arcs represent the cost per call, while their capacities represent the maximum number of calls that can be made across these lines. Point-to-point demands exist on this network, stating the number of calls that must be routed to and from each pair of nodes. The operator seeks to complete all demand requests on the network at a minimum total cost. (This is an example of a *multi-commodity flow network*, since demands are specific to node pairs.) Now, suppose that an interdicting agent has the capability of destroying any k arcs in the network. The interdictor seeks a set of k arcs which, when removed from the system, results in the

largest optimal objective function value for the operator. Note that the interdicator is *maximizing* the minimum cost for the operator, and hence this problem belongs to the class of *maximin* problems (minimax problems can be dealt with similarly).

The most transparent applications of network interdiction invoke military or antiterrorism scenarios. Indeed, as we will discuss later in this article, network interdiction models are very well suited to address problems arising in this context. The interdicator's budget can be tailored to the model under consideration, and can reflect the relative difficulty of interdicting certain network assets. Hence, if a terrorist can reasonably launch a simultaneous attack on four soft targets or two fortified targets, then one can state a constraint that (the number of soft target attacks) + 2 (the number of fortified target attacks) ≤ 4 . It is also a reasonable assumption that terrorists or military enemies will seek to optimally disrupt an operator's objective function value. The assumption of perfect information is valid for two reasons. One, underestimating an enemy's ability to gain information (or to make a lucky guess) could leave the network vulnerable to a devastating attack. Two, in a surprising number of network applications, detailed information is very much available to the public [2].

However, network interdiction is most generally applied to situations in which vulnerability to any kind of disruption is possible. Natural disasters do not intentionally seek to exploit weaknesses in infrastructure, but may very well do so by accident. A network operator may wish to guarantee a certain level of system performance against any of a possible set of scenarios. In the telecommunication network example above, even if terrorism is of no concern, accidents or random equipment failure may drive the operator to consider the strategic addition of redundant infrastructure. To guarantee that the network remain functional even if any three links fail, one may consider a "conceptual" interdicator with a budget of three arcs that can be destroyed. When more general failure probabilities are associated with a network, one can guarantee that the

network remains operational with probability $0 < \tau < 1$ using network interdiction concepts. Let C be the set of network components (including perhaps nodes and arcs), and define x_i to be the interdicator's binary variable that equals 1 if component i of the network is disrupted, and 0 otherwise, for all $i \in C$. Let the probability of component i operating successfully be given by $p_i, \forall i \in C$, and assume that all component failures are independent. The interdicator in this case is constrained to create a failure event whose probability does not exceed $(1 - \tau)$. This means that the interdicator's choice of x must be such that

$$\prod_{i \in C} (1 - p_i)^{x_i} \leq (1 - \tau), \quad (1a)$$

or

$$\sum_{i \in C} \log(1 - p_i) x_i \geq \log(1 - \tau). \quad (1b)$$

The interdiction budget thus takes on the form given in Equation (1b).

One final note on the benefits of interdiction models is relevant at this point. A time-honored tradition in assessing the vulnerability of systems relies on enumerating disaster scenarios and counting all possible things that can go wrong in a network. Considering a network having n components, of which at most k can fail, one would have to enumerate and evaluate $\sum_{\ell=1}^k \binom{n}{\ell}$ possible failure events, which is computationally prohibitive for modest values of n and k . Representing such problems as network interdiction problems results in models that are solvable by much more efficient algorithms than exhaustive enumeration.

In the section titled "Interdiction Problem Classes," we discuss various classes of interdiction models and applications. Then, in the section titled "Fortification against Interdiction," we extend these models to allow the network operator to first design and/or fortify an existing network, keeping in mind the subsequent actions of an interdicator. This article closes with the section titled "Summary and Future Challenges" with a brief discussion of prominent challenges in the field.

INTERDICTION PROBLEM CLASSES

We begin this section by examining a general model for studying interdiction problems. Observe here that interdiction does not need to be specific to network models, but could be applied in any Stackelberg optimization problem. Let the interdictor's decisions be given by vector x , and let the operator's recourse decisions be given by y . Then the interdictor's problem can be given by

$$\sup f(x) \quad (2a)$$

$$\text{s.t. } x \in X, \quad (2b)$$

where X is a set of feasible interdiction solutions, and where $f(x)$ is given by

$$f(x) = \inf g(x, y) \quad (3a)$$

$$\text{s.t. } y \in Y(x), \quad (3b)$$

where $g(x, y)$ is an objective function based on inputs x and decision variables y , and where $Y(x)$ is a feasible region based on inputs x . (Observe that since $f(x)$, $g(x, y)$, X , and $Y(x)$ are defined generally, we thus use “sup” rather than “max” to handle cases in which a maximum does not exist in Equation (2a); similarly, we use “inf” rather than “min” in Equation (2b).)

Just as in any other class of optimization problems, interdiction research examines special structures and assumptions on Models (2) and (3) above. A listing of some such problem specializations is given below.

Maximum Flow Interdiction

The maximum flow interdiction problem takes place on a network with a designated source node s and sink node t . Each arc has a capacity, but no flow cost. The objective is to find a set of flows from s to t that obey flow balance and capacity constraints, and move as much total flow from s to t as possible. Since the operator's goal is to maximize flow, the interdictor has the goal of minimizing the operator's maximum flow (casting this as a minimax, rather than a maximin, problem).

Perhaps not surprisingly, the theory of linear programming duality addresses one

important aspect of interdiction via the *max-flow/min-cut* theorem. Define a cut as a set of arcs that disconnect s from t when removed from the network (i.e., no directed path from s to t would remain in the network), and define the weight of this cut as the sum of all arc capacities in the cut. Then the maximum flow in the network equals the minimum weight cut; if budget is given in terms of total capacity that can be removed from the network, one can easily optimize the maximum flow interdiction problem by identifying this cut (which is polynomially achievable by maximum flow algorithms) and removing capacity from this cut.

Alternatively, if the interdictor is restricted on the *number* of arcs that may be removed from the network, the problem becomes much more difficult. One solution approach considers a dual formulation of the maximum flow problem, which when coupled with interdiction decisions, yields a nonlinear mixed-integer programming problem. The nonlinear terms are quadratic, and since at least one variable in each quadratic term is constrained to be binary valued, the problem can be linearized and solved as a linear mixed-integer program. The work of Wood [3] presents these ideas in technical detail, and lays the foundation for broader network interdiction analysis.

Shortest Path Interdiction

In the shortest path interdiction problem, network arcs are associated with flow costs, but not capacities. The operator seeks a shortest path from a source node s to a sink node t , that is, one whose sum of arc flow costs is minimized over all possible paths. The interdictor, in a maximin framework, wishes to take some action to maximize the operator's shortest path cost. Interdiction in this situation usually refers to eliminating arcs or increasing costs on certain arcs. These problems can be algorithmically addressed in much the same way as the maximum flow problems.

For critical path (CP) networks, one actually seeks the longest path in a network as described above. CP networks model the completion of a complex project by representing individual tasks as arcs, and milestones as

nodes. Before any task represented by an arc (i,j) can commence, all tasks entering node i must be completed. These restrictions model the precedence relationships among tasks. For instance, in publishing a book, one must wait for (i) the arrival of copyright permissions and (ii) the corrected manuscript, before a milestone of having the right to publish is achieved. After this milestone is reached, one can then begin the tasks of (iii) printing the book and (iv) releasing certain specific details of the book to potential consumers. Arc weights refer to corresponding task durations, and the entire project is completed only when all tasks are completed and the last milestone is reached. The last milestone cannot be reached faster than the length of any path from the source to the destination, since each path represents a chain of events that must be done sequentially; hence, the project completion time is given by the longest path in the network. While the longest path problem is typically quite difficult to solve, it is polynomially solvable in this context since CP networks are necessarily acyclic. The interdiction problem here can seek to select a set of possible task duration delays that maximize the longest path in the network.

A closely related problem may analyze a network in which arc weights are bounded between 0 and 1, and refer to the probability of successfully traversing the arc. The operator may thus seek a most-reliable path in the network, assuming independent arc reliabilities. Using a similar operation as shown in Equations (1a) and (1b), we can convert this problem to a shortest path problem (where arc costs are in terms of logarithms of arc probabilities). Interdiction in this context seeks to minimize the maximum probability of traversing the network from the source to the destination. While the interdicator is typically seen as an antagonist seeking to sow destruction in the network, one can easily imagine the operator to be a fugitive, with the interdicator acting as a policing agency reducing the operator's chances of remaining undetected.

Indeed, an excellent example of this application comes in the deployment of nuclear sensors in the former Soviet republics [4].

These nuclear sensors are designed to detect smugglers of nuclear material. With the establishment of the Second Line of Defense (SLD) in 1998, an optimization challenge was presented to deploy sensors on components of the network. The presence of a sensor would decrease the reliability of successfully traversing a link on which the sensor was located (or, if the sensor is placed on a node, it would decrease the probability of successfully traversing any arc coming into the node). We discuss extensions of this research in the context of fortification actions in the section titled "Fortification against Interdiction" (3).

Minimum Cost and Multicommodity Flow Interdiction

The minimum cost flow interdiction problem generalizes the previous models. In the minimum cost flow interdiction problem, arc costs and capacities are given, along with supplies and demands at every node. The operator will exhaust all excess supplies and satisfy all demands at every node, while obeying the capacity constraints on the arcs and minimizing overall flow costs. The interdicator will take an interdiction action to maximize the operator's minimum overall flow cost.

For instance, one could model a military materiel mobilization system as a network in which supply nodes contain reserve materiel, and demand nodes require receipt of this materiel. As long as materiel is considered to be one homogeneous item, issuing supplies across the network can be modeled as a minimum cost flow problem. An enemy may wish to cripple this network by deleting a strategic set of arcs that optimally hinders the deployment of materiel.

On the other hand, if materiel is not homogeneous, then one must consider point-to-point demands of different classes of items (e.g., tanks, artillery, fuel, and personnel). Since different nodes will have varying supplies/demands of these items, one must consider a multicommodity flow version of this problem. (See also the point-to-point telecommunication model given above for another multicommodity flow example.) For this case,

Lim and Smith [5] provide integer programming and duality-based procedures for optimizing multicommodity flow interdiction.

Asymmetric Goals and Information

It is possible that information about the underlying network may be viewed differently by the interdictor and operator, or that the interdictor and operator have different objectives. In this case, the interdictor/operator framework is altered somewhat. Maintaining the follower problem (Eq. 3), we would revise the interdictor's problem as

$$\sup f'(x, y) \quad (4a)$$

$$\text{s.t. } x \in X \quad (4b)$$

$$y \text{ optimizes the operator's} \\ \text{problem (Eq. 3).} \quad (4c)$$

Note that Equation (4c) requires a set of constraints to guarantee that the operator acts optimally. The field of mathematical programming with equilibrium constraints (MPEC) deals with these conditions, often requiring that the y -solution be a part of a Karush–Kuhn–Tucker (KKT) point to Problem (3), if KKT conditions are necessary and sufficient to optimize Problem (3). (See Ref. 6 for a review of MPEC literature.) Also, note that given a value of x , there may be multiple solutions $y \in \hat{Y}(x)$ that optimize Problem (3). The formulation (Eq. 4) optimizes, for the interdictor, over *all* $y \in \hat{Y}(x)$, which implies that the operator is willing to break ties in favor of the interdictor. In this sense, Equation (4) is optimistic for the interdictor [see the work of Bayrak and Bailey [7] or Smith *et al.* [8] for instances in which this assumption has been made].

The problem setup above is often used when the interdictor simply does not have all relevant information, or when the operator has been able to successfully conceal certain aspects of the network components. However, when the interdiction objective differs from the operator's objective, it is possible to represent many different types of nonadversarial behavior. A famous example of this arises in toll-pricing and revenue management [9]. The interdictor may be licensed to

install toll booths and control toll prices at certain points in a network. In response, an assumption is made that the operators (independently operating entities in the system) react to minimize a combination of travel time and tolls. A revenue-seeking interdictor may attempt to maximize revenue from the traffic network. A benevolent interdictor may attempt to improve traffic. It is well known that independent agents across a network will seek their fastest route home and converge to a traffic equilibrium that is sub-optimal, in the sense that the average time required to complete travel is larger than the minimum possible average travel time if the agents were centrally controlled. By strategically interdicting the network and adding prices to roadways (arcs), an interdictor can induce better traffic flows.

FORTIFICATION AGAINST INTERDICTION

Once a proper understanding of interdiction models and techniques is obtained, it is possible to consider fortification decisions on behalf of the operator that anticipate potential interdiction decisions and mitigate their effectiveness. These problems could protect against terrorist actions, improve the reliability of network components, or insure against the loss of certain components. In this section, we provide a brief discussion of fortification problems occurring in the network interdiction literature.

We begin here by discussing a design/fortification problem on multicommodity flow networks, which can be used to analyze the general problem of fortifying networks such as maximum flow, shortest path, critical path, and minimum cost flow networks. These problems now take the form of a three-stage optimization problem. The operator acts first to construct a network, or to fortify existing network infrastructure. In some variations of the problem, the operator may also be required to transmit an initial set of flows through the network. This would be the case when, for instance, an interdiction action is uncertain, and the effectiveness of the network before interdiction should be considered in the decision-making stage.

Following the network design phase, an interdicator acts to eliminate some set of arcs (within an interdiction budget), and the operator sends recourse flows through the remaining network. These models are either “min-max-min” or “max-min-max” models in practice. [Smith *et al.* [8] describe a “max-min-max” model of this form.]

Indeed, as shown in the section titled “Asymmetric Goals and Information,” one need not assume that the interdicator has the same goals as the operator. The interdicator could be acting greedily to destroy components of the network that have the most capacity, or those that transmit the most flows possible. This suboptimal enemy behavior might be due to the desire of the interdicator to make a dramatic attack on the network, or could reflect the interdicator’s lack of ability (due to partial information or time restrictions) to optimize an attack.

These fortification problems are often very difficult due to the three-stage representation. For simplified models, it may be possible to incorporate a compact linear model that represents two simultaneous actions. For instance, consider an emergency relief center location and protection model. There exist a set of client locations in some domain that must be covered by an emergency facility location (e.g., a fire station, hospital, or police station). Once an emergency takes place in any one of the client locations, service is provided from whichever facility is closest to the client. The location model would therefore minimize the expected amount of time to respond to an emergency, weighted perhaps by the importance of serving each of the client nodes and the likelihood of an emergency occurring at the nodes. An interdicator may act first to remove some combination of facilities, thus maximizing the minimum expected time for responding to these emergencies.

In this scenario, the fortification problem would therefore select a set of established facilities that could not be interdicted to minimize expected response time, assuming that optimal interdiction actions follow on unfortified facilities. Instead of modeling this as a three-stage (min-max-min) problem, Church and Scaparra [10] formulate a single mixed-integer linear program that

simultaneously captures the final two stages of the game (interdiction and facility-to-client assignment). This formulation is possible due to the special structure of the problem under investigation; namely, that client nodes are served by a direct assignment to facilities.

One recent development in the field of fortification regards the *prioritization* of fortification assets [11]. An implicit assumption has been made to this point that the operator’s budget for network design/fortification is known. (The same assumption is made for the interdicator, but this is justified owing to the conservative nature of critical network protection problems.) Some real-world implementations of fortification decisions do not implement all fortification decisions at once, but rather do so as budgets permit. Conceptually, considering assets labeled $\{a_1, \dots, a_7\}$, it is possible that the optimal fortification decision with a budget of protecting three assets would protect a_1 , a_2 , and a_3 . However, with a budget of four assets that can be protected, the complement of this subset, $\{a_4, \dots, a_7\}$, may become optimal to protect. It is generally suboptimal to give a priority list to an agency that orders the importance of fortifying assets. However, priority lists are often unavoidable due to practical considerations regarding budget uncertainty. Therefore, an optimal policy given a probability distribution of how much budget will be available for fortifying assets is of considerable practical value.

As a final remark to this section, we note that alternative models exist for certain design/fortification problems having special structures. When link failures are of sufficiently small probability (and nodes are reliable), one may consider only the event in which any single link can fail. While this model fits into the prior discussion of design/fortification problems, one can use problem-specific information to model and solve the problem in a more efficient fashion. One such problem minimizes the cost of adding enough links to a network such that a path exists between every pair of nodes (or, perhaps, a feasible general network flow exists across the entire network) even in the face of any single-arc failure [12]. Another considers the design of synchronous optical

networks (SONETs), which are inherently resistant to single-arc failures [13].

SUMMARY AND FUTURE CHALLENGES

Network interdiction studies are typically multistage games in which an interdicting agent alters certain network components in order to optimally hinder a network operator. These interdiction actions often consist of eliminating network arcs, and are limited in scope by cardinality or budget restrictions. These problems are often solved from the interdictor's perspective by maximizing damage to the network, subject to constraints forcing the interdictor to prepare against optimal operator decisions. These constraints are either logically generated on the basis of the special structure of the problem under consideration, or by considering the dual formulation of the operator's problem when the strong duality theorem applies to the operator's problem. Fortification decisions can then be considered prior to these interdiction models, which help assess where strategic resources should be deployed to protect against an intelligent interdicting agent. It is important to note that the interdicting agent need not be a malicious entity, but may instead be a worst-case accident due to random failures or natural disasters.

There are many avenues for continued development of interdiction models, but perhaps the most pressing regards multistage games, in which fortification and defense actions are alternated over a finite horizon. If these games are not trivial extensions of two- or three-stage problems (i.e., if they do not simply rebuild and destroy the same components over time), they cannot be solved using technology that currently exists. Multistage optimization problems are notoriously difficult, and even three-stage models can be quite difficult to address computationally. Similarly, we note that interdiction does not necessarily occur at discrete points. Especially for a multistage fortification/interdiction application, the timing of interdiction and fortification actions is an important decision aspect. Noting the suboptimality of a priority list, the interdictor

may choose to hold back interdiction actions at the present time, allowing the operator to have a longer time frame in which the network can be used without damage. In return, the interdictor could collect more information about their available interdiction budget, and make a more effective interdiction action later in the scenario. Likewise, if fortification budgets are also uncertain at the beginning of the time horizon, the operator may strategically deploy fortification decisions gradually at certain time points, rather than all at once.

Magdeburg, Magdeburg,
Germany

A *polyhedron* is the intersection of finitely many affine halfspaces, where an *affine halfspace* is a set

$$H^{\leq}(a, \beta) = \{x \in \mathbb{R}^n : \langle a, x \rangle \leq \beta\}$$

for some $a \in \mathbb{R}^n$ and $\beta \in \mathbb{R}$ (here, $\langle a, x \rangle = \sum_{j=1}^n a_j x_j$ denotes the standard scalar product on $\mathbb{R}^n$). Thus, every polyhedron is the set

$$P^{\leq}(A, b) = \{x \in \mathbb{R}^n : Ax \leq b\}$$

of feasible solutions to a system $Ax \leq b$ of linear inequalities for some matrix $A \in \mathbb{R}^{m \times n}$ and some vector $b \in \mathbb{R}^m$. Clearly, all sets $\{x \in \mathbb{R}^n : Ax \leq b, A'x = b'\}$ are polyhedra as well, as the system $A'x = b'$ of linear equations is equivalent to the system $A'x \leq b'$, $-A'x \leq -b'$ of linear inequalities. A bounded polyhedron is called a *polytope* (where *bounded* means that there is a bound which no coordinate of any point in the polyhedron exceeds in absolute value).

Polyhedra are of great importance for operations research, because they are not only the sets of feasible solutions to linear programs (LP), for which we have beautiful duality results and both practically and theoretically efficient algorithms, but also the solution of (mixed) integer linear programming (MILP) problems can be reduced to linear optimization problems over polyhedra. This relationship has to a large extent formed the backbone of the extremely successful story of MILP and combinatorial optimization over the last few decades.

In the section titled “The Geometry of Polyhedra”, we review those parts of the general theory of polyhedra that are most important with respect to optimization questions,

while in the section titled “Polyhedra and Integrality” we treat concepts that are particularly relevant for integer programming. Most of the “basic polyhedral theory” today is standard textbook knowledge. In the section titled “Pointers to Literature”, for some of the results we provide references to the original papers. There, we also give pointers to proofs of the theorems mentioned in the first two sections, where we mainly refer to the beautiful book by Schrijver [1]. There are, of course, many other excellent treatments of the theory of polyhedra with respect to optimization questions, for example, in the recent survey by Conforti *et al.* [2], in the handbook articles by Schrijver [3] and Burkard [4], as well as in the books by Nemhauser and Wolsey [5], Grötschel *et al.* [6], Bertsimas and Wets [7], Cook *et al.* [8], Wolsey [9], Korte and Vygen [10], or Barvinok [11]. The books by Ziegler [12], and Grünbaum [13] are the most important sources for the general geometric and combinatorial theory of polyhedra, in particular of polytopes. We also refer to the handbook article by Gritzmann and Klee [14] as well as to the one by Bayer and Lee [15].

THE GEOMETRY OF POLYHEDRA

Some Notations

We define $[p] = \{1, \dots, p\}$ and denote by $\mathbb{R}_+ = \{\alpha \in \mathbb{R} : \alpha \geq 0\}$, the set of nonnegative real numbers. A *submatrix* of $M \in \mathbb{R}^{m \times n}$ is a matrix $M_{I,J} \in \mathbb{R}^{I \times J}$ for some $\emptyset \neq I \subseteq [m]$ and $\emptyset \neq J \subseteq [n]$ formed by the rows and columns of M indexed by the elements of I and J , respectively. In particular, $M_{i,j} \in \mathbb{R}$ is the entry in row i and column j . We write $M_{I,*} = M_{I,[n]}$ and $M_{*,J} = M_{[m],J}$, in particular, $M_{i,*} \in \mathbb{R}^n$ and $M_{*,j} \in \mathbb{R}^m$ are the i th row and the j th column of M , respectively. The *kernel* of $M \in \mathbb{R}^{m \times n}$ is $\ker(M) = \{x \in \mathbb{R}^n : Mx = \mathbb{0}\}$. The *identity matrix* $\text{Id}_n \in \mathbb{R}^{n \times n}$ has one-entries on its main diagonal and zeroes elsewhere.

For $x \in \mathbb{R}^n$ and $J \subseteq [n]$, the vector formed by the components of x indexed by elements of J is denoted by $x_J \in \mathbb{R}^J$. We consider, in the

context of matrix multiplication, all vectors as column vectors, and use $(\cdot \cdot \cdot)^t$ to refer to the transposed matrix or vector. We denote the zero vector in $\mathbb{R}^n$ by $\mathbb{0} \in \mathbb{R}^n$ and the standard unit vector by $e_i \in \mathbb{R}^n$, having its i th component equal to one, all other components being zero.

Denoting the set of all determinants of submatrices (formed by arbitrary subsets of rows and columns of equal cardinality, including the empty submatrix, whose determinant is considered to be one) of a matrix $M \in \mathbb{R}^{m \times n}$ by $\delta(M)$, we define

$$\Delta(M) = \left\{ \frac{p}{q} : p, q \in \delta(M) \cup (-\delta(M)), q \neq 0 \right\},$$

and, for every finite set $\emptyset \neq V \subseteq \mathbb{R}^n$, we set $\Delta(V) = \Delta(M)$, where M is any matrix whose set of columns is V . Clearly, for rational matrices $M \in \mathbb{Q}^{m \times n}$ and (finite) sets $V \subseteq \mathbb{Q}^n$ we have $\Delta(M), \Delta(V) \subseteq \mathbb{Q}$.

The *encoding length* of $\alpha = \frac{p}{q} \in \mathbb{Q}$ with $p, q \in \mathbb{Z}$ relatively prime is

$$\langle \alpha \rangle = 1 + \lceil \log_2(|p| + 1) \rceil + \lceil \log_2(|q| + 1) \rceil.$$

For a rational vector $v \in \mathbb{Q}^n$ and a rational matrix $M \in \mathbb{Q}^{m \times n}$, we define

$$\begin{aligned} \langle v \rangle &= n + \sum_{j=1}^n \langle v_j \rangle \quad \text{and} \\ \langle M \rangle &= mn + \sum_{i=1}^m \sum_{j=1}^n \langle M_{i,j} \rangle. \end{aligned}$$

Moreover, we denote the maximum encoding length of any entry in M by $\langle M \rangle_{\max}$, as well as the maximum encoding length of all components of vectors in the finite set $V \subseteq \mathbb{Q}^n$ by $\langle V \rangle_{\max}$.

Basics

Most important, every polyhedron $P \subseteq \mathbb{R}^n$ is *convex*, that is, for all $x, y \in P$ and $\alpha \in [0, 1]$, we have $\alpha x + (1 - \alpha)y \in P$ as well. Moreover, polyhedra are topologically closed subsets of $\mathbb{R}^n$.

As the solution sets to finite systems of linear inequalities, polyhedra generalize affine subspaces, which are the solution sets to

systems of linear equations. The criterion for $Ax = b$ not being solvable via the existence of some multiplier vector $\lambda \in \mathbb{R}^m$ with $\lambda^t A = \mathbb{0}$ and $\langle \lambda, b \rangle \neq 0$ generalizes to systems of linear inequalities in the following way (where both parts of the theorem easily follow from each other).

Theorem 1 [Farkas Lemma]. *For each $A \in \mathbb{R}^{m \times n}$ and $b \in \mathbb{R}^m$ the following hold:*

- (i) *Either $Ax \leq b$ is solvable or there is some $\lambda \in \mathbb{R}_+^m$ with $\lambda^t A = \mathbb{0}$ and $\langle \lambda, b \rangle < 0$ (but not both).*
- (ii) *Either $Ax = b, x \geq \mathbb{0}$ is solvable or there is some $\lambda \in \mathbb{R}^m$ with $\lambda^t A \geq \mathbb{0}$ and $\langle \lambda, b \rangle < 0$ (but not both).*

It turns out that the “crucial solutions” to systems of linear inequalities are obtained as the unique solutions of certain nonsingular linear equation systems, whose components are well known to be expressible in the following way.

Theorem 2 [Cramer’s rule]. *If $A \in \mathbb{R}^{n \times n}$ is nonsingular, then, for every $b \in \mathbb{R}^n$, the unique solution $x \in \mathbb{R}^n$ with $Ax = b$ is given by*

$$x_j = \frac{\det(A_{*,1}, \dots, A_{*,j-1}, b, A_{*,j+1}, \dots, A_{*,n})}{\det(A)}$$

for all $j \in [n]$.

The following estimates follow from the Leibniz formula for determinants.

Theorem 3. *There is a constant $C > 0$ such that the estimates*

$$\langle \alpha \rangle \leq C \cdot n^2 \cdot \langle M \rangle_{\max} \quad \text{for all } \alpha \in \Delta(M)$$

and

$$\langle \beta \rangle \leq C \cdot n^2 \cdot \langle V \rangle_{\max} \quad \text{for all } \beta \in \Delta(V)$$

hold for all $M \in \mathbb{Q}^{m \times n}$ and for all finite sets $V \subseteq \mathbb{Q}^n$.

Polyhedral and Finitely Generated Cones

A *cone* is a subset $K \subseteq \mathbb{R}^n$ with $\mathbb{0} \in K$ and $\alpha y \in K$ for all $y \in K$ and $\alpha \in \mathbb{R}_+$. A *polyhedral cone* is a polyhedron that is a cone, or, equivalently, a polyhedron $P^\leq(A, \mathbb{0})$ for some $A \in \mathbb{R}^{m \times n}$.

The (convex) *conic hull* of a subset $X \subseteq \mathbb{R}^n$ is the cone

$$\text{ccone}(X) = \left\{ \sum_{x \in X'} \alpha_x x : X' \subseteq X, |X'| < \infty, \right. \\ \left. \alpha_x \geq 0 \text{ for all } x \in X' \right\}$$

(with $\text{ccone}(\emptyset) = \{\mathbb{0}\}$) of all *conic combinations* of the vectors in X . A cone $K \subseteq \mathbb{R}^n$ is *finitely generated*, if there is a finite set $X \subseteq \mathbb{R}^n$ with $K = \text{ccone}(X)$. Every vector in a conic hull can be obtained by a conic combination of few generators.

Theorem 4 [Carathéodory's Theorem, conic version]. *For each $X \subseteq \mathbb{R}^n$ and $y \in \text{ccone}(X)$ there is a linearly independent subset $X' \subset X$ (in particular, $|X'| \leq n$) with $y \in \text{ccone}(X')$.*

The Farkas-Lemma (Part (ii) of Theorem 1) yields a separation theorem for finitely generated cones.

Theorem 5. *If $y \notin \text{ccone}(X)$ for the finite set $X \subseteq \mathbb{R}^n$, then there is some $a \in \mathbb{R}^n$ with*

$$\langle a, x \rangle \leq 0 < \langle a, y \rangle \text{ for all } x \in \text{ccone}(X)$$

(i.e., $\text{ccone}(X) \subseteq H^\leq(a, 0)$, but $y \notin H^\leq(a, 0)$).

The following result implies that every polyhedral cone is finitely generated, which is of utmost importance for the theory of polyhedra.

Theorem 6. *For every matrix $A \in \mathbb{R}^{m \times n}$, there is a finite set $X \subseteq (\Delta(A))^n$ with*

$$P^\leq(A, \mathbb{0}) = \text{ccone}(X).$$

The *polar* of a cone $K \subseteq \mathbb{R}^n$ is the convex cone

$$K^\circ = \{a \in \mathbb{R}^n : \langle a, x \rangle \leq 0 \text{ for all } x \in K\}.$$

The polar of a finitely generated cone $\text{ccone}(X)$ with a finite set $X \subseteq \mathbb{R}^n$ is obviously the polyhedral cone

$$(\text{ccone}(X))^\circ = \{a \in \mathbb{R}^n : \langle x, a \rangle \leq 0 \text{ for all } x \in X\}. \quad (1)$$

From Theorem 5, we also obtain

$$(P^\leq(A, \mathbb{0}))^\circ = \text{ccone}\{A_{1,*}, \dots, A_{m,*}\} \quad (2)$$

for each $A \in \mathbb{R}^{m \times n}$.

Moreover, from Theorem 5, one deduces $(\text{ccone}(X))^{\circ\circ} = \text{ccone}(X)$, from which one finds, by applying Theorem 6 as well as Equation (1) (two times), the following reverse statement to Theorem 6.

Theorem 7. *For every finite set $X \in \mathbb{R}^n$, there is a matrix $A \in (\Delta(X))^{m \times n}$ with*

$$\text{ccone}(X) = P^\leq(A, \mathbb{0}).$$

The Fundamental Structure of Polyhedra

The *homogenization* of a polyhedron $P^\leq(A, b) \subseteq \mathbb{R}^n$ (with $A \in \mathbb{R}^{m \times n}$, $b \in \mathbb{R}^m$) is the polyhedral cone

$$\text{homog}(P^\leq(A, b)) = \{(x, \xi) \in \mathbb{R}^n \oplus \mathbb{R} : Ax - \xi b \leq \mathbb{0}, \xi \geq 0\}.$$

Applying Theorem 6 to $\text{homog}(P^\leq(A, b))$ as well as Theorem 7 to the finitely generated cone

$$\text{ccone}(\{(x, 1) \in \mathbb{R}^n \oplus \mathbb{R} : x \in X\} \cup \{(y, 0) \in \mathbb{R}^n \oplus \mathbb{R} : y \in Y\})$$

for finite sets $X, Y \subseteq \mathbb{R}^n$, one obtains the following representation theorem for polyhedra, where

$$\text{conv}(X) = \left\{ \sum_{x \in X'} \alpha_x x : X' \subseteq X, |X'| < \infty, \right. \\ \left. \sum_{x \in X'} \alpha_x = 1, \alpha_x \geq 0 \text{ for all } x \in X' \right\}$$

denotes the *convex hull* of a set $X \subseteq \mathbb{R}^n$, and

$$S + T = \{s + t : s \in S, t \in T\}$$

is the *Minkowski sum* of $S, T \subseteq \mathbb{R}^n$.

Theorem 8 [Weyl–Minkowski Theorem].

- (i) For every $A \in \mathbb{R}^{m \times n}$ and $b \in \mathbb{R}^m$ there are finite sets $X, Y \subseteq (\Delta(A, b))^n$ with

$$P^{\leq}(A, b) = \text{conv}(X) + \text{ccone}(Y). \quad (3)$$

- (ii) For all finite sets $X, Y \subseteq \mathbb{R}^n$ there are $A \in (\Delta(X \cup Y))^{m \times n}$ and $b \in (\Delta(X \cup Y))^m$ with

$$\text{conv}(X) + \text{ccone}(Y) = P^{\leq}(A, b). \quad (4)$$

Thus, polyhedra can be represented by *outer descriptions* (intersections of finitely many affine halfspaces) and by *inner descriptions* (Minkowski sums of a polytope and a finitely generated cone). Clearly, algebraically an outer description may contain both linear inequalities and linear equations. Depending on the context, one type of description of a polyhedron can be significantly more convenient to deal with than the other. For instance, from inner descriptions one concludes readily that images of polyhedra under linear maps are polyhedra as well (see the section titled “Projections of Polyhedra”). In turn, the fact that also preimages of polyhedra under linear maps are polyhedra is easy to prove via outer descriptions. From outer descriptions of polyhedra, one also finds immediately that intersections of finitely many polyhedra are polyhedra.

A *rational polyhedron* is a polyhedron for which A and b , or, equivalently, X and Y , in Equations (3) and (4) can be chosen to be rational matrices, vectors, and sets, respectively. Denoting, for a rational polyhedron $P \subseteq \mathbb{R}^n$, by $\langle P \rangle_{\max}^{\text{outer}}$ the smallest number α such that there is an outer description $P = P^{\leq}(A, b)$ of P with a rational matrix A and a rational vector b with $\langle(A, b)\rangle_{\max} \leq \alpha$, and by $\langle P \rangle_{\max}^{\text{inner}}$ the smallest number β such that there is an inner description $P = \text{conv}(X) + \text{ccone}(Y)$ of P with rational finite sets

$X, Y \subseteq \mathbb{Q}^n$ with $\langle X \cup Y \rangle_{\max} \leq \beta$, we obtain the following result from Theorem 3.

Theorem 9. *There is a constant $C > 0$ such that*

$$\begin{aligned} \langle P \rangle_{\max}^{\text{inner}} &\leq C \cdot n^2 \cdot \langle P \rangle_{\max}^{\text{outer}} \quad \text{and} \\ \langle P \rangle_{\max}^{\text{outer}} &\leq C \cdot n^2 \cdot \langle P \rangle_{\max}^{\text{inner}} \end{aligned}$$

hold for every rational polyhedron $P \subseteq \mathbb{R}^n$.

In particular, whenever the rational system $Ax \leq b$ (with $A \in \mathbb{Q}^{m \times n}$ and $b \in \mathbb{Q}^m$) has any solution, then it also has a solution whose encoding length is bounded by a polynomial in $\langle(A, b)\rangle$. This shows that the linear programming feasibility problem is contained in the complexity class NP, and, via Theorem 1, also in coNP. (Of course, it is well known that this problem is even solvable in polynomial time).

However, the smallest possible number of inequalities $Ax \leq b$ in an outer description and the smallest possible cardinalities of the sets X and Y in an inner description of a rational polyhedron P are not bounded polynomially by each other, in general.

The *characteristic cone* (or *recession cone*) of a polyhedron $P \subseteq \mathbb{R}^n$ is

$$\begin{aligned} \text{char}(P) = \\ \{y \in \mathbb{R}^n : x + \text{cone}\{y\} \subseteq P \text{ for all } x \in P\}. \end{aligned}$$

Theorem 10. *If $\emptyset \neq P = P^{\leq}(A, b) = \text{conv}(X) + \text{ccone}(Y) \subseteq \mathbb{R}^n$ is a polyhedron (with $A \in \mathbb{R}^{m \times n}$, $b \in \mathbb{R}^m$, and $X, Y \subseteq \mathbb{R}^n$ finite), then we have*

$$\text{ccone}(Y) = \text{char}(P) = P^{\leq}(A, \mathbb{O}).$$

The *lineality space* of a polyhedron $P \subseteq \mathbb{R}^n$ is the largest linear subspace

$$\text{lineal}(P) = \text{char}(P) \cap (-\text{char}(P))$$

contained in $\text{char}(P)$.

Theorem 11. *For a polyhedron $\emptyset \neq P = P^{\leq}(A, b)$ (with $A \in \mathbb{R}^{m \times n}$, $b \in \mathbb{R}^m$) we have*

$$\text{lineal}(P) = \ker(A).$$

A nonempty polyhedron $\emptyset \neq P \subseteq \mathbb{R}^n$ with lineality space $\text{lineal}(P) = \{\mathbb{O}\}$ is called *pointed*. For most purposes, it is sufficient to consider pointed polyhedra. In fact, if a polyhedron has a nontrivial lineality space $L \neq \{\mathbb{O}\}$, then, in most contexts, it is sufficient to investigate instead of P its orthogonal projection to the orthogonal complement of L , which is a pointed polyhedron. Therefore, subsequently we mainly consider pointed polyhedra. For instance, all polyhedra that are contained in the nonnegative orthant $\mathbb{R}_+^n$ as well as all polytopes are pointed.

Faces of Polyhedra

For $a \in \mathbb{R}^n \setminus \{\mathbb{O}\}$ and $\beta \in \mathbb{R}$, we denote the boundary hyperplane of the affine halfspace $H^\leq(a, \beta)$ by

$$H^=(a, \beta) = \{x \in \mathbb{R}^n : \langle a, x \rangle = \beta\}.$$

A (proper) face of a polyhedron $P \subseteq \mathbb{R}^n$ is the intersection $F = P \cap H^=(a, \beta)$ of P with the boundary hyperplane of some halfspace $H^\leq(a, \beta) \supseteq P$ containing P . The face F is said to be *defined* by the inequality $\langle a, x \rangle \leq \beta$ in this case. In addition, $\emptyset$ and P themselves are considered (*trivial*) faces of P (defined by $\langle \mathbb{O}, x \rangle \leq -1$ and $\langle \mathbb{O}, x \rangle \leq 0$, respectively). Nonempty faces are particularly important for optimization, because they are the (nonempty) sets of optimal solutions to linear optimization problems over polyhedra.

The following result (which is a generalization of Part (i) of Theorem 1) provides a characterization of those inequalities that are valid for (and thus define faces of) a nonempty polyhedron.

Theorem 12. *Let $A \in \mathbb{R}^{m \times n}$, $b \in \mathbb{R}^m$, $a \in \mathbb{R}^n$, and $\beta \in \mathbb{R}$ with $P = P^\leq(A, b) \neq \emptyset$. The inequality $\langle a, x \rangle \leq \beta$ is valid for (all x in) P if and only if there is some $\lambda \in \mathbb{R}_+^m$ with $\lambda^t A = a$ and $\langle \lambda, b \rangle \leq \beta$.*

Every face $F \neq \emptyset$ of a polyhedron $P = P^\leq(A, b) = \text{conv}(X) + \text{ccone}(Y)$ (with $A \in \mathbb{R}^{m \times n}$, $b \in \mathbb{R}^m$, and $X, Y \subseteq \mathbb{R}^n$ finite) is a polyhedron as well with

$$F = \text{conv}(X \cap F) + \text{ccone}(Y \cap \text{char}(F)).$$

Moreover, with

$$I = \text{Eq}_{Ax \leq b}(F) = \{i \in [m] : F \subseteq H^=(A_{i,*}, b_i)\},$$

we have $F = \{x \in P : A_{I,*}x = b_I\}$, and, conversely, for every $I \subseteq [m]$, the set $F = \{x \in P : F \subseteq H^=(A_{I,*}, b_i)\}$ is a face of P with $I \subseteq \text{Eq}_{Ax \leq b}(F)$.

In particular, every polyhedron has finitely many faces. Partially ordered by inclusion, they form the *face lattice* $\mathcal{L}(P)$ of P (including $\emptyset$ and P). For each face $F \neq \emptyset$ of the polyhedron P we have $\text{lineal}(F) = \text{lineal}(P)$. Hence, the (nonempty) faces of pointed polyhedra are pointed polyhedra as well.

The maximal elements in $\mathcal{L}(P) \setminus \{P\}$ are called the *facets* of P . A face of P is a facet if and only if $\dim(F) = \dim(P) - 1$ holds (where the *dimension* $\dim(P)$ of a polyhedron is the affine dimension of its affine hull $\text{aff}(P)$). The minimal elements in $\mathcal{L}(P) \setminus \{\emptyset\}$ for a pointed polyhedron P are called the *vertices* of P . The vertices of a polyhedron P are the faces of dimension zero, that is, the faces that contain exactly one point (which, of course, is also called *vertex*).

Theorem 13. *For a point $v \in P$ in a polyhedron $P = P^\leq(A, b)$ (with $A \in \mathbb{R}^{m \times n}$ and $b \in \mathbb{R}^m$) the following statements are pairwise equivalent.*

1. *The point v is a vertex of P .*
2. *There are no two points $x, x' \in P \setminus \{v\}$ with $v \in \text{conv}\{x, x'\}$.*
3. *There is some $I \subseteq [m]$, $|I| = n$ such that $A_{I,*}$ is nonsingular with $v = A_{I,*}^{-1}b_I$.*

A pointed polyhedral cone K has exactly one vertex, namely $\mathbb{O}$, and therefore, one is more interested in the minimal elements of $\mathcal{L}(K) \setminus \{\emptyset, \{\mathbb{O}\}\}$, which are called the *extreme rays* of K . The extreme rays of a (pointed) polyhedral cone are its faces of dimension one. The one-dimensional unbounded faces of a general pointed polyhedron are called its *extreme rays*; the one-dimensional bounded faces are the *edges*. The edges of a pointed polyhedron P are of the form $\text{conv}\{v, w\}$ with two vertices $v \neq w$ of P , and every extreme

ray of P can be written as $v + R$ with a vertex v of P and an extreme ray R of $\text{char}(P)$ (which is pointed if P is pointed).

An outer description $P = \{x \in \mathbb{R}^n : A^\leq x = b^\leq, A^\leq x \leq b^\leq\}$ of a polyhedron P is *irredundant* if removing any equation or any inequality from the system results in a different (larger) polyhedron, and turning any inequality in the system into an equation results in a different (smaller) polyhedron.

Theorem 14. *Let $\emptyset \neq P \subseteq \mathbb{R}^n$ be a polyhedron, $A^{(1)} \in \mathbb{R}^{m(1) \times n}$, $b^{(1)} \in \mathbb{R}^{m(1)}$, $A^{(2)} \in \mathbb{R}^{m(2) \times n}$, and $b^{(2)} \in \mathbb{R}^{m(2)}$ with*

$$P \subseteq \{x \in \mathbb{R}^n : A^{(1)}x = b^{(1)}, A^{(2)}x \leq b^{(2)}\} \quad (5)$$

such that, for all $i \in [m(2)]$, we have $P \not\subseteq H^=(A^{(2)}_{i,}, b_i)$.*

- (i) *Equality in Equation (5) holds if and only if*
 - $\text{aff}(P) = \{x \in \mathbb{R}^n : A^{(1)}x = b^{(1)}\}$, and
 - *for each facet F of P , there is an $i \in [m(2)]$ such that $\langle A^{(2)}_{i,*}, x \rangle \leq b_i$ defines the facet F of P .*
- (ii) *If equality holds in Equation (5), then the right-hand side of Equation (5) is an irredundant outer description of P if and only if*
 - $A^{(1)}$ has full row rank, and
 - *the inequalities in $A^{(2)}x \leq b^{(2)}$ define pairwise distinct facets of P .*

An inner description $P = \text{conv}(X) + \text{ccone}(Y)$ of a polyhedron P is *irredundant* if removing any point from X or any vector from Y results in a different (smaller) polyhedron.

Theorem 15. *Let $\emptyset \neq P \subseteq \mathbb{R}^n$ be a pointed polyhedron, and let $X, Y \subseteq \mathbb{R}^n$ be finite sets with $X \subseteq P$ and $Y \subseteq \text{char}(P)$.*

- (i) *We have $P = \text{conv}(X) + \text{ccone}(Y)$ if and only if*
 - X contains all vertices of P , and
 - Y contains a nonzero vector from each extremal ray of $\text{char}(P)$.

- (ii) *If $P = \text{conv}(X) + \text{ccone}(Y)$ holds, then $\text{conv}(X) + \text{ccone}(Y)$ is an irredundant inner description of P if and only if*

- X is the set of vertices of P , and
- Y contains exactly one nonzero vector from each extremal ray of $\text{char}(P)$.

As for a pointed polyhedron $P = \text{conv}(X) + \text{ccone}(Y)$ (with finite sets $X, Y \subseteq \mathbb{R}^n$, $c \in \mathbb{R}^n$, and $\omega = \max\{\langle c, x \rangle : x \in P\}$, we have $\omega = \infty$ if $\langle c, y \rangle > 0$ for some $y \in Y$, and $\omega = \max\{\langle c, x \rangle : x \in X\}$ otherwise, Theorem 15 implies that a bounded linear optimization problem over a pointed polyhedron P attains its optimum in a vertex of P .

Projections of Polyhedra

We mentioned above that the projection $P = \pi(Q)$ of a polyhedron $Q \subseteq \mathbb{R}^d$ via a linear map $\pi : \mathbb{R}^d \rightarrow \mathbb{R}^n$ with $\pi(y) = Ty$ for a matrix $T \in \mathbb{R}^{n \times d}$ is a polyhedron, as, for all $X, Y \subseteq \mathbb{R}^d$, we have

$$\begin{aligned} \pi(\text{conv}(X) + \text{ccone}(Y)) \\ = \text{conv}(\pi(X)) + \text{ccone}(\pi(Y)). \end{aligned}$$

We say that a face F of Q is π -compatible if it can be defined by an inequality $\langle T^t a, y \rangle \leq \beta$ (valid for Q) for some $a \in \mathbb{R}^n$.

Theorem 16. *For a polyhedron $Q \subseteq \mathbb{R}^d$, a linear projection $\pi : \mathbb{R}^d \rightarrow \mathbb{R}^n$, and the polyhedron $P = \pi(Q)$, the map defined via $F \mapsto \pi(F)$ is an isomorphism between the sublattice of $\mathcal{L}(Q)$ formed by the π -compatible faces and $\mathcal{L}(P)$.*

An extended formulation for a polyhedron $P \subseteq \mathbb{R}^n$ is an outer description $Q = P^\leq(A, b)$ of some polyhedron $Q \subseteq \mathbb{R}^d$ along with a linear projection $\pi : \mathbb{R}^d \rightarrow \mathbb{R}^n$ with $\pi(Q) = P$. Such an extended formulation of a polyhedron P can be much simpler (e.g., in terms of the number of inequalities) than any outer description of P if the complexity of the facets of P is hidden in lower dimensional parts of the face lattice $\mathcal{L}(Q)$ (see Theorem 16). As owing to

$$\begin{aligned} \max \{\langle c, x \rangle : x \in P\} &= \max \{\langle T^t c, y \rangle : y \in Q\} \\ (\text{for all } c \in \mathbb{R}^n), \end{aligned}$$

linear optimization problems over $P = \pi(Q)$ can be solved by solving linear optimization problems over Q , extended formulations play an important role in modern mathematical optimization [16].

We conclude the first part of the article by considering the question of how to derive an outer description of a polyhedron from an extended formulation. Here, the fundamental result follows via Theorem 12.

Theorem 17. *Let $Q = P^\leq(D, g) \subseteq \mathbb{R}^d$ be a polyhedron with $D \in \mathbb{R}^{q \times d}$ and $g \in \mathbb{R}^q$, suppose the linear projection $\pi : \mathbb{R}^d \rightarrow \mathbb{R}^n$ is defined via $\pi(y) = Ty$ for a matrix $T \in \mathbb{R}^{n \times d}$ and all $y \in \mathbb{R}^d$, and let $\bar{T}$ be any matrix whose rows form a basis of $\ker(T)$.*

If $L \in \mathbb{R}_+^{m \times d}$ is a matrix whose rows generate the projection cone

$$\begin{aligned} \left\{ \lambda \in \mathbb{R}_+^q : \lambda^t (D\bar{T}^t) = \mathbb{0} \right\} \\ = \text{ccone} \{ L_{1,*}, \dots, L_{m,*} \}, \end{aligned}$$

then every $A \in \mathbb{R}^{m \times n}$ with $AT = LD$ satisfies

$$\pi(Q) = P^\leq(A, b) \cap \pi(\mathbb{R}^d)$$

with $b = Lg$.

If, in the situation of Theorem 17, the projection $\pi : \mathbb{R}^d \rightarrow \mathbb{R}^n$ is the orthogonal projection to the first n coordinates, then the projection cone is simply

$$\left\{ \lambda \in \mathbb{R}_+^q : \langle D_{*,j}, \lambda \rangle = 0 \text{ for all } j \in [d] \setminus [n] \right\}, \quad (6)$$

and A can be chosen to consist of the first n columns of LD . Furthermore, if $n = d - 1$ holds, then a finite generating system for the projection cone (6) can be obtained from the relation:

$$\begin{aligned} \left\{ \lambda \in \mathbb{R}_+^{r+s} : \sum_{i=1}^{r+s} \lambda_i \delta_i = 0 \right\} \\ = \text{ccone} \{ \delta_k e_\ell - \delta_\ell e_k : k \in [r], \ell \in [r+s] \setminus [r] \}, \end{aligned}$$

for all numbers $\delta_1, \dots, \delta_r > 0 > \delta_{r+1}, \dots, \delta_{r+s}$ (which one can easily establish by induction on $r + s$).

Theorem 18 [Fourier–Motzkin elimination]. *For a polyhedron $Q = P^\leq(D, g) \subseteq \mathbb{R}^d$ (with $B \in \mathbb{R}^{q \times d}$ and $g \in \mathbb{R}^q$) and the sets*

$$I^{>0} = \{i \in [q] : D_{i,d} > 0\}$$

$$I^=0 = \{i \in [q] : D_{i,d} = 0\}$$

$$I^{<0} = \{i \in [q] : D_{i,d} < 0\},$$

the polyhedron in $\mathbb{R}^{d-1}$ arising from Q by orthogonal projection to the first $d - 1$ coordinates is the set of all $x \in \mathbb{R}^{d-1}$ that satisfy the following system:

$$\begin{aligned} \langle D_{i,*}, x \rangle &\leq g_i \quad \text{for all } i \in I^{>0} \\ \langle D_{k,d} D_{\ell,*} - D_{\ell,d} D_{k,*}, x \rangle &\leq D_{k,d} g_\ell - D_{\ell,d} g_k \\ &\quad \text{for all } k \in I^{>0}, \ell \in I^{<0}. \end{aligned}$$

By applying the Fourier–Motzkin elimination method (Theorem 18) iteratively, one can compute an outer description of a polyhedron's orthogonal projection to any coordinate subspace from an outer description of the polyhedron. Note that the sizes of the descriptions may blow up exponentially (even if, after each iteration, one removes redundant constraints).

The case of general projections can be solved by Fourier–Motzkin elimination as follows, where we adopt the notation discussed earlier. Let $\tilde{n}$ be the rank of T , and assume that the submatrix $T_{[\tilde{n}], [\tilde{n}]}$ of T is nonsingular. Denoting the nonsingular matrix that equals $T_{\tilde{n},*}$ on its first $\tilde{n}$ rows and that has the vectors e_i , for $i = \tilde{n} + 1, \dots, d$, in its other rows by $\tilde{T} \in \mathbb{R}^{d \times d}$, and the orthogonal projection to the first $\tilde{n}$ coordinates by $\tilde{\pi} : \mathbb{R}^d \rightarrow \mathbb{R}^{\tilde{n}}$, we have $\pi(y)_{[\tilde{n}]} = \tilde{\pi}(\tilde{T}y)$ for all $y \in \mathbb{R}^d$. Thus, with $\tilde{D} = D\tilde{T}^{-1}$ and $\tilde{Q} = P^\leq(\tilde{D}, g)$, we find $P = \{x \in \pi(\mathbb{R}^d) : x_{\tilde{n}} \in \tilde{\pi}(\tilde{Q})\}$.

One reason for the interest in computing projections of polyhedra is that one can convert inner to outer and outer to inner description by means of such computations. Indeed, it follows from the discussion of homogenization and the concept of polarity that all such conversions can be done by any method that computes, for a given finite set $X \subseteq \mathbb{R}^n$, a matrix $A \in \mathbb{R}^{m \times n}$ with $\text{ccone}(X) = P^\leq(A, \mathbb{0})$ (see Theorem 7). Denoting by $T \in \mathbb{R}^{n \times d}$ a

matrix whose set of columns is X , we have, by definition, $\text{ccone}(X) = \pi(Q)$, where $\pi : \mathbb{R}^d \rightarrow \mathbb{R}^n$ is the projection defined via $\pi(y) = Ty$ for all $y \in \mathbb{R}^d$ and $Q = \mathbb{R}_+^d$. Thus, computing an outer description of $\pi(Q)$ from the outer description $\mathbb{R}_+^d = P^\leq(-\text{Id}_d, \mathbb{O})$ of Q solves the problem.

POLYHEDRA AND INTEGRALITY

Integral points in polyhedra play a crucial role in integer linear programming and combinatorial optimization. The fundamental concept here is the *integer hull*

$$P_I = \text{conv}(P \cap \mathbb{Z}^n)$$

of a polyhedron $P \subseteq \mathbb{R}^n$. In this second part, we describe the most fundamental results on integer hulls, which are important, since, on the one hand, they satisfy

$$\max\{\langle c, x \rangle : x \in P \cap \mathbb{Z}^n\} = \max\{\langle c, x \rangle : x \in P_I\}$$

for all $c \in \mathbb{R}^n$, while on the other hand, as convex objects, they are much more convenient to deal with than the discrete sets $P \cap \mathbb{Z}^n$. In particular, we treat *integral polyhedra*, that is, polyhedra P with $P_I = P$. Identifying a polyhedron P as integral is particularly pleasant, as in this case integer linear optimization problems over P can be treated as (continuous) linear optimization problems over P .

Theorem 19. *For $A \in \mathbb{Q}^{m \times n}$ and $b \in \mathbb{Q}^m$, defining an integral polyhedron $P^\leq(A, b)$, one can, for every $c \in \mathbb{Q}^n$, find $x^* \in P^\leq(A, b) \cap \mathbb{Z}^n$ with*

$$\langle c, x^* \rangle = \max\{\langle c, x \rangle : x \in P^\leq(A, b) \cap \mathbb{Z}^n\}$$

(or conclude that no such x^* exists) in time bounded by a polynomial in $\langle A \rangle + \langle b \rangle + \langle c \rangle$.

Integer Points in Polyhedra

Similarly to the parameterization (3) of points in a polyhedron by an inner description, for a *rational* polyhedron P , we can also

parameterize the set of all *integral* points in P . For a finite set $Y \subseteq \mathbb{R}^n$, we denote by

$$\text{mono}(Y) = \left\{ \sum_{y \in Y} \alpha_y y : \alpha_y \in \mathbb{N} \text{ for all } y \in Y \right\}$$

(with $\mathbb{N} = \{0, 1, 2, \dots\}$), the submonoid of $\mathbb{R}^n$ which is generated by Y .

Theorem 20. *For every rational polyhedron $P \subseteq \mathbb{R}^n$ there are finite sets $X, Y \subseteq \mathbb{Z}^n$ with*

$$P \cap \mathbb{Z}^n = X + \text{mono}(Y) \quad \text{and}$$

$$\text{char}(P) = \text{ccone}(Y),$$

such that $\langle X \cup Y \rangle_{\max}$ is bounded by a polynomial in n and $\langle P \rangle_{\max}^{\text{inner}}$ (and thus, by a polynomial in n and $\langle P \rangle_{\max}^{\text{outer}}$).

A finite set $H \subseteq \mathbb{Z}^n$ is called an *integral Hilbert basis* (of $\text{ccone}(H)$) if

$$\text{ccone}(H) \cap \mathbb{Z}^n = \text{mono}(H)$$

holds. The existence statement of the following theorem is a special case of Theorem 20.

Theorem 21. *Every rational polyhedral cone K has an integral Hilbert basis; if K is pointed, then the integral Hilbert basis of K is uniquely determined.*

Moreover, Theorem 20 implies that whenever the rational system $Ax \leq b$ (with $A \in \mathbb{Q}^{m \times n}$ and $b \in \mathbb{Q}^m$) has any integral solution, it also has an integral solution whose encoding length is bounded by a polynomial in $\langle (A, b) \rangle$. This shows that the integer linear programming feasibility problem is contained in the complexity class NP (it is, however, not in coNP, unless $\text{NP} = \text{coNP}$).

Finally, from Theorem 20 one can derive that the integral hulls of *rational* polyhedra are rational polyhedra as well.

Theorem 22. *For each rational polyhedron $P \subseteq \mathbb{R}^n$, the integer hull P_I of P is a rational polyhedron, for which $\langle P_I \rangle_{\max}^{\text{outer}}$ is bounded by a polynomial in n and $\langle P \rangle_{\max}^{\text{outer}}$.*

The number of facets of P_I is, however, in general not bounded polynomially in the number of facets of P . Furthermore, the integer hull of a nonrational polyhedron need not even be a polyhedron (see, e.g., $P = \{(x_1, x_2) \in \mathbb{R}^2 : x_2 \leq \sqrt{2}x_1, x_1 \geq 1\}$).

A generalization of Theorem 22 to *mixed-integer hulls* of rational polyhedra holds as well: If $P \subseteq \mathbb{R}^n$ is a rational polyhedron, then $\text{conv}\{x \in P : x_J \in \mathbb{Z}^J\}$ is a rational polyhedron for every $J \subseteq [n]$.

We end this section by a crucial criterion for integrality of (pointed rational) polyhedra.

Theorem 23. *A pointed rational polyhedron is integral (i.e., $P_I = P$) if and only if all vertices of P are integral.*

Total Dual Integrality

A rational system $Ax \leq b$ with $A \in \mathbb{Q}^{m \times n}$ and $b \in \mathbb{Q}^m$ defining a nonempty polyhedron $P^\leq(A, b) \neq \emptyset$ is called *totally dual integral (TDI)* if, for every $c \in \mathbb{Z}^n$ with $\max\{c, x\} : Ax \leq b\} < \infty$, there is some $y^* \in \mathbb{N}^m$ with $A^t y^* = c$ and

$$\langle b, y^* \rangle = \min \{ \langle b, y \rangle : A^t y = c, y \in \mathbb{R}_+^m \},$$

that is, the dual problem to $\max\{c, x\} : Ax \leq b\}$ has an integral optimal solution y^* . It is convenient to consider all rational systems $Ax \leq b$ with $P^\leq(A, b) = \emptyset$ TDI as well.

Theorem 24. *A system $Ax \leq b$ with integral matrix $A \in \mathbb{Z}^{m \times n}$ and rational right-hand side vector $b \in \mathbb{Q}^m$ is TDI if and only if, for every face $F \neq \emptyset$ of $P^\leq(A, b)$, the set*

$$\{A_{i,*} : i \in \text{Eq}_{Ax \leq b}(F)\}$$

is an integral Hilbert basis.

Applying Theorem 21 to the rational normal cones

$$\{c \in \mathbb{R}^n : \langle c, x^* \rangle = \max \{ \langle c, x \rangle : x \in P \} \text{ for all } x^* \in F\}$$

of the (minimal) faces F of a rational polyhedron P , one can construct TDI systems as in the following result.

Theorem 25. *Let $P \subseteq \mathbb{R}^n$ be a rational polyhedron.*

1. *There is an integral matrix $A \in \mathbb{Z}^{m \times n}$ and a rational vector $b \in \mathbb{Q}^m$ with $P = P^\leq(A, b)$ such that $Ax \leq b$ is TDI, where b can be chosen to be integral if P is integral.*
2. *If there is a rational matrix $A \in \mathbb{Q}^{m \times n}$ and an integral vector $b \in \mathbb{Z}^m$ with $P = P^\leq(A, b)$ such that $Ax \leq b$ is TDI, then P is integral.*

Thus, every rational polyhedron admits an outer descriptions by a TDI-system with integral (left-hand-side) coefficient matrix, though, in general, this will not be an irredundant description in the sense of the section titled “Faces of Polyhedra”. Nevertheless, such a description can provide much structural insight, for example, within the theory of cutting planes for nonintegral polyhedra. The algorithmic problem, however, to decide whether a given rational system $Ax \leq b$ is TDI is coNP-complete (even for A restricted to the set of node-edge incidence matrices, see the section titled “Total Unimodularity,” of undirected graphs).

Outer descriptions of (integral) polyhedra with integral right-hand side vectors are very important, as, due to Theorem 25(2) (and the definition of TDI), they yield strong duality relations for certain integer linear optimization problems.

Theorem 26. *If the system $Ax \leq b$ is TDI with $A \in \mathbb{Q}^{m \times n}$ and an integral right-hand side $b \in \mathbb{Z}^m$, and $P = P^\leq(A, b) \neq \emptyset$ holds, then, for every $c \in \mathbb{Z}^n$ with $\max\{c, x\} : x \in P\} < \infty$, we have*

$$\begin{aligned} \max\{c, x\} : Ax \leq b, x \in \mathbb{Z}^n\} \\ = \min\{\langle b, y \rangle : A^t y = c, y \geq 0, y \in \mathbb{Z}^m\}. \end{aligned} \quad (7)$$

Total Unimodularity

A matrix $A \in \{-1, 0, 1\}^{m \times n}$ is *totally unimodular (TU)* if all square submatrices of A have determinant -1 , 0 , or 1 . The (version for pointed polyhedra of the) following result is a consequence of Theorem 23 and Theorem 13

(see Part 3) obtained by using Cramer's rule (Theorem 2).

Theorem 27. *If $A \in \{-1, 0, 1\}^{m \times n}$ is totally unimodular and $b \in \mathbb{Z}^m$ is integral, then $P^\leq(A, b)$ is an integral polyhedron.*

If $A \in \{-1, 0, 1\}^{m \times n}$ is TU, then so are all submatrices of A , (A, Id_m) , $(A, -A)$, and A^t , where the latter allows the following conclusion from Theorem 27.

Theorem 28. *If $A \in \{-1, 0, 1\}^{m \times n}$ is totally unimodular, then, for every $b \in \mathbb{Q}^m$, the system $A \leq b$ is TDI.*

In particular, if $A \in \{-1, 0, 1\}^{m \times n}$ is TU, then the strong duality relation (7) holds for all integral $b \in \mathbb{Z}^m$ and $c \in \mathbb{Z}^n$ (for which the respective optimal values are finite).

The following criterion is extremely useful for establishing total unimodularity of matrices.

Theorem 29 [Criterion of Ghouila-Houri]. *A matrix $A \in \{-1, 0, 1\}^{m \times n}$ is totally unimodular if and only if, for every subset $I \subseteq [m]$ of row indices, there is a partitioning $I = I^+ \uplus I^-$ (with $I^+ \cap I^- = \emptyset$) such that*

$$\sum_{i \in I^+} A_{i,*} - \sum_{i \in I^-} A_{i,*} \in \{-1, 0, 1\}^n$$

holds. (Clearly, a similar characterization via all subsets of column indices holds.)

From Theorem 29 one readily deduces that every matrix with entries from $\{-1, 0, 1\}$ that has at most one positive and at most one negative entry per column is TU. In particular, the *node-arc incidence matrix* $\text{inc}(D) \in \{-1, 0, 1\}^{V \times A}$ of a directed graph $D = (V, A)$ (with $A \subseteq V \times V$, defined via

$$\text{inc}(D)_{v,a} = \begin{cases} -1 & \text{if } a = (v, w) \text{ for some } w \in V \\ 1 & \text{if } a = (u, v) \text{ for some } u \in V \\ 0 & \text{otherwise} \end{cases}$$

for all $v \in V$ and $a \in A$, is TU. Thus, the set

$$\{x \in \mathbb{R}^A : \text{inc}(D)x = 0, \ell \leq x \leq u\}$$

of *circulations* in D respecting the *integral* lower and upper bounds $\ell, u \in \mathbb{Z}^A$ is an integral polytope.

The *node-edge incidence matrix* $\text{inc}(G) \in \{0, 1\}^{V \times E}$ of an undirected graph $G = (V, E)$ is defined via

$$\text{inc}(G)_{v,e} = \begin{cases} 1 & \text{if } e = \{v, w\} \text{ for some } w \in V \\ 0 & \text{otherwise} \end{cases}$$

for all $v \in V$ and $e \in E$. Theorem 29 yields that the node-edge incidence matrix of a graph $G = (V, E)$ is TU if and only if the graph is bipartite; that is, there is a partitioning $V = S \uplus T$ (with $S \cap T = \emptyset$) such that $E \subseteq \{\{s, t\} : s \in S, t \in T\}$. In particular, the matching polytope of a bipartite graph $G = (V, E)$ (i.e., the convex hull of the characteristic vectors $\chi(M) \in \{0, 1\}^E$ —with $\chi(M)_e = 1$ if and only if $e \in M$ —of all *matchings* $M \subseteq E$ —with $e \cap e' = \emptyset$ for all $e, e' \in M, e \neq e'$) has

$$\begin{aligned} \sum_{e \in E: v \in e} x_e &\leq 1 && \text{for all } v \in V \\ x_e &\geq 0 && \text{for all } e \in E \end{aligned}$$

as an outer description.

The most important class of TU matrices is formed by the *network matrices*. Such a network matrix $N \in \{-1, 0, 1\}^{A_T \times A}$ arises from a directed graph $D = (V, A)$ and a subset $A_T \subseteq A$ of $|V| - 1$ arcs that, viewed as undirected edges, form a spanning tree on V , by setting, for each $a' \in A_T$ and $a = (v, w) \in A$,

$$N_{a',a} = \begin{cases} 1 & \text{if the } v-w \text{ path in } A_T \text{ uses } a' \text{ in} \\ & \text{forward direction} \\ -1 & \text{if the } v-w \text{ path in } A_T \text{ uses } a' \text{ in} \\ & \text{backward direction} \\ 0 & \text{otherwise} \end{cases}$$

Theorem 30. *Network matrices are totally unimodular.*

In fact, network matrices are the crucial building blocks of the whole class of totally unimodular matrices, as every totally unimodular matrix arises from network

matrices and two special totally unimodular 5×5 matrices by certain operations that preserve total unimodularity. From such structural results, one can derive polynomial time algorithms for testing matrices A for total unimodularity (while, as remarked at the end of the section “Total Dual Integrality,” testing a system $Ax \leq b$ for total dual integrality is coNP-complete).

POINTERS TO LITERATURE

Whenever possible, we provide, for the results mentioned in the article, pointers to proofs in Schrijver [1], which is also a great source for historical notes and many more references than listed here.

The Farkas-Lemma (Theorem 1) dates back to work by Farkas as well as by Minkowski at the end of the 19th century [1, Section 7.3]. There are several possibilities to prove the theorem. In fact, the Farkas-Lemma is a special case of more general separation theorems in convex analysis [17, Chapter 2]. A particularly nice and purely linear algebraic proof was given by Conforti *et al.* [18], who derive the Farkas-Lemma from the corresponding obstruction of the solvability of linear equation systems. Theorem 2 was proposed by Cramer (1750); see Schrijver [1, Section 3.1]. Theorem 3 follows from Schrijver [1, Theorem 3.2]; see also Edmonds [19]. In 1911, Theorem 4 was proved by Carathéodory [20]; see also Schrijver [1, Theorem 7.1]. Theorems 6–8 have their origins in the work of Farkas, Minkowski [21], and Weyl [22]; see also Schrijver [1, Section 7.2]. The statements on the components of the vectors and on the entries of the matrices (as well as Theorem 9) follow, for example, from (the proofs in) Schrijver [1, Section 10.2]. An elementary proof of Theorem 6 can be found in Kaibel [23]; see also Schrijver [1, Corollary 7.1a]. For proofs of Theorems 10 and 11 (on the characteristic cones and lineality spaces of polyhedra), we refer to Schrijver [1, Section 8.2]. Theorem 12 is present as Corollary 7.1h in Schrijver [1]. For the other statements in the section titled “Faces of Polyhedra,” see Schrijver [1, Sections 8.3–8.9]. Theorem 16

is folklore (we are not aware of any other explicit reference, thus we refer to Kaibel [24]). Theorem 17 is usually formulated for orthogonal projections to coordinate subspaces only [2, Section 2.4]. An explicit proof in the general setting can be found in Kaibel [24]. The Fourier–Motzkin method (Theorem 18) is treated in Schrijver [1, Section 12.2]. The method was devised by Motzkin [25], where the idea goes back to the work of Fourier in the early 19th century. For the algorithmic problem of converting representations of polyhedra, we refer to the survey by Seidel [26] and to the software system `polymake` by Gawrilow and Joswig [27] (<http://www.opt.tu-darmstadt.de/polymake/>).

The proof of Theorem 19 relies on the fact that both (continuous) linear programs [28] as well as systems of linear Diophantine equations can be solved in polynomial time [1, Theorem 16.2]. For proofs of Theorems 20–22, we refer to Schrijver [1, Sections 16.2–16.4 and 17.2]. The fact that the integer hull of a rational polyhedron is a rational polyhedron (Theorem 22) was proposed by Meyer [29], and the notion of *Hilbert bases* has been introduced by Giles and Pulleyblank [30], where the ideas of the proof of Theorem 21 date back to Gordan [31]. The concept of *total dual integrality* has been invented by Edmonds and Giles [32,33]. See Schrijver [1, Section 22.3] for proofs of Theorems 24 and 25 (the results being provided by Giles and Pulleyblank [30] and Schrijver [34]). The coNP-hardness of the TDI-property has been established by Ding *et al.* [35]. Proofs of the results on total unimodularity can be found in Schrijver [1, Chapter 19]. The connection between TU matrices and integral polyhedra (Theorem 27 and a similar characterization of total unimodularity) was established by Hoffman and Kruskal [36]. Theorem 29 has been proved by Ghouila-Houri [37]. The total unimodularity of network matrices (Theorem 30) was suggested by Tutte [38]. The decomposition theorem for TU matrices mentioned after Theorem 30 has been proved by Seymour [39]. Cunningham and Edmonds [40] derived a polynomial time test for total unimodularity from that theorem; the asymptotically fastest known algorithm is due to Truemper [41].

INTRODUCTION

Consider the integer programming (IP) feasibility problem in the form

$$\text{Find } x \in \mathbb{Z}^n : x \in P, \quad (\text{IP})$$

where P is a polyhedron described by inequalities. The work of Lenstra in 1979 [1] answered one of the most challenging questions in the theory of integer programming by presenting an algorithm to solve (IP), whose running time is polynomial, when n , the dimension is fixed. This paper pioneered the use of lattice basis reduction in integer programming, and initiated an interest in polynomial results in integer programming under the “fixed dimension” assumption. Somewhat later Kannan developed an improved variant [2,3], which—to date—has the best theoretical complexity for integer programming feasibility.

The goal of this survey is to review lattice-based methods to solve (IP), focusing on Lenstra’s and Kannan’s algorithms, which are by now considered “classical,” and the more recent reformulation methods of Aardal *et al.* [4], and Krishnamoorthy and Pataki [5].

Example 1. As motivation, let us consider a “hard” IP feasibility problem

$$\begin{aligned} 460 &\leq 51x_1 + 49x_2 \leq 489 \\ 0 &\leq x_1, x_2 \leq 10 \\ x_1, x_2 &\in \mathbb{Z}, \end{aligned} \quad (1)$$

shown in Fig. 1. One can see by inspection that it is infeasible.

Let us denote by P the underlying polyhedron. The hyperplanes

$$\{x \mid x_1 = k\} \ (k = 0, \dots, 9)$$

all intersect P , so branch-and-bound trying to prove infeasibility generates 10 subproblems, when branching on x_1 . Branching on x_2 also leads to 10 subproblems.

We will return to this example later, in particular, in the section titled “Reformulation Methods” we show that the rangespace reformulation of Krishnamoorthy and Pataki [5] creates an equivalent feasibility problem, in which the set $\{y \mid y_2 \in \mathbb{Z}\}$ has empty intersection with the underlying polyhedron, hence branching on y_2 solves the problem at the root node.

A lattice L is the set of integral combinations of linearly independent vectors defined as

$$L = \mathbb{L}(B) = \{Bx : x \in \mathbb{Z}^r\} \subseteq \mathbb{R}^n. \quad (2)$$

The matrix B has r independent columns, which are said to form a *basis* of $\mathbb{L}(B)$. We call r the *dimension* of L , and when $r = n$ we say that L is *full dimensional*. Writing $b_1, \dots, b_r \in \mathbb{R}^n$ for the columns of B , we also denote L by $\mathbb{L}(b_1, \dots, b_r)$.

The common theme in lattice-based methods is transforming (IP) into a problem of the form

$$\text{Find } y \in \mathbb{Z}^r : By \in Q, \quad (\text{IP}_{B,Q})$$

where the matrix B and the polyhedron Q are suitably chosen, so the problem of finding a point in $P \cap \mathbb{Z}^n$ is translated into finding one

Figure 1. The instance of Example 1.

in $Q \cap \mathbb{L}(B)$. We emphasize that the choice of B and Q is specific to each method, but in all of them, the polyhedron Q has favorable geometry, and B has short and near orthogonal columns, which form a *reduced* basis of $\mathbb{L}(B)$ in a sense to be made precise later. These two facts will allow us to prove good complexity bounds on solving $(IP_{B,Q})$.

The classical (Lenstra’s and Kannan’s) algorithms are recursive. They branch on the last few variables in $(IP_{B,Q})$, that is, enumerate all possible integer values that these can attain, then construct new B matrices and Q polyhedra for each of the resulting subproblems, and so on. However, Mehrotra and Li [6] recently presented a restructuring of the computations in Lenstra’s algorithm, so that branching on the last variable in $(IP_{B,Q})$ is translated back to branching on a suitable hyperplane in the original problem. In contrast, the reformulation methods run a full branch-and-bound algorithm on $(IP_{B,Q})$, and are implemented by simply feeding the formulation to a commercial IP solver.

The *nullspace reformulation method*, which is applicable to equality constrained integer programs was proposed by Aardal *et al.* [4]. Later, Krishnamoorthy and Pataki [5] introduced the *rangespace reformulation method* for general integer programs. One

can analyze these methods on a family of knapsack feasibility problems, with the coefficient vector of the knapsack constraint decomposing as $a = \lambda p + r$, where p and r are integral vectors, and λ is a large integer. There are a variety of instances that fit into this framework with three interesting properties: (i) they are difficult for branch-and-bound that branches on the x_i variables; (ii) their infeasibility is proven by branching on px ; and (iii) when λ is sufficiently large, branching on the last variable in the reformulations has the same effect as branching on px in the original problem.

There is a compelling history of these instances, dating back to Jeroslow’s famous problem from 1974 [7]. An analysis of nullspace reformulation assuming such decomposable structure was given by Aardal and Lenstra [8,9]. Krishnamoorthy and Pataki [5] showed how a variety of knapsack problems starting with Jeroslow’s problem satisfy properties (i) and (ii), presented a “recipe” to generate such instances, and proved Property (iii) for both reformulations.

A recent result of Pataki *et al.* [10] shows that when branch-and-bound is applied to the reformulation of bounded integer programs, the majority of instances get solved without generating any subproblems, that

is, at the root node. This result may seem counterintuitive; however, it fits in nicely with the previous work on “low density” subset sum problems, which have been widely used in cryptography.

The rest of the survey is divided into five sections. In the rest of the introduction we describe key definitions that will be used throughout the paper. In the section titled “Reduced Bases” we describe reduced bases of lattices. In the section titled “The Geometry of Lattices and Convex Sets” we present a lemma due to Lenstra on the geometry of lattices, and convex sets, which will play a role in the analysis of both the classical, and the reformulation methods. In the section titled “Lenstra’s and Kannan’s Algorithms” we review Babai’s improved version [11] of Lenstra’s algorithm, and Kannan’s algorithm. Kannan’s algorithm is less frequently covered in surveys than Lenstra’s method, perhaps because it is more technical: we think that we succeeded in giving a simplified treatment. In the section titled “Reformulation Methods” we review the reformulation methods, with their complexity analyses. In the section titled “Further Reading and Computational Testing” we point to further reading, and review computational results obtained by lattice-based methods.

The emphasis of the survey is providing simple proofs of complexity results, illustrative examples, and a unifying view of the classical and the reformulation methods. For instance, we will continue Example 1, and show how Lenstra’s algorithm, and the rangespace reformulation handle this “difficult” instance. We include exercises, and we think that the survey will be suitable to teach a two- to three-class long segment on lattice-based methods in a course on Integer Programming.

A reader may be interested either only in Lenstra’s and Kannan’s algorithms, or only in the reformulation methods; so for convenience, sections titled “Lenstra’s and Kannan’s Algorithms” and “Reformulation Methods” can be read independently of each other.

Exercise 1. Generalize Example 1 by showing that for positive integers λ and μ with $\lambda \geq 2\mu + 1$, the integer programming problem

$$\begin{aligned} \lambda\mu - \lambda + \mu &\leq (\lambda + 1)x_1 + (\lambda - 1)x_2 \leq \lambda\mu - \mu - 1 \\ 0 &\leq x_1, x_2 \leq \mu \\ x_1, x_2 &\in \mathbb{Z} \end{aligned} \quad (3)$$

is infeasible, and branching either on x_1 or x_2 will generate at least μ subproblems.

Important Definitions

Branch-and-bound, which we abbreviate as B&B, is a classical solution method for (IP); it was first proposed by Land and Doig [12]. It starts with P as the sole subproblem (node). In a general step, one chooses a subproblem P' , a variable x_i , and creates nodes $P' \cap \{x|x_i = \gamma\}$, where γ ranges over all possible integer values of x_i . We repeat this until all subproblems are shown to be empty, or we find an integral point in one of them.

Sometimes we will *branch on hyperplanes* to solve (IP): given a nonzero integral vector p , we let

$$\begin{aligned} k_{\max} &= \max \{px \mid x \in P\}, \\ k_{\min} &= \min \{px \mid x \in P\}, \end{aligned} \quad (4)$$

and create the subproblems

$$P \cap \{x \mid px = \lfloor k_{\max} \rfloor\}, \dots, P \cap \{x \mid px = \lceil k_{\min} \rceil\}.$$

The number of subproblems is the *integer width* of P along p , that is,

$$\text{iwidth}(p, P) = \lfloor k_{\max} \rfloor - \lceil k_{\min} \rceil + 1.$$

In particular, if $\text{iwidth}(p, P) = 0$, then (IP) is infeasible, and we say that *its infeasibility is proven by branching on px* . Analogously, the *width* of P along p is defined as

$$\text{width}(p, P) = k_{\max} - k_{\min}.$$

To emphasize the difference between Land and Doig’s branch-and-bound algorithm, and branching on hyperplanes, we call the former method *ordinary branch-and-bound*.

It is well known [13] that if A is a rational matrix with n columns, then

$$\mathbb{N}(A) := \{x \in \mathbb{Z}^n \mid Ax = 0\} \quad (5)$$

is also a lattice, and we call this set the *null-lattice* of A .

We call a matrix U *unimodular*, if it is square, integral, and has determinant ± 1 .

For a convex set Q we write $r(Q)$ for the radius of the largest ball in the affine hull of Q that can be inscribed in Q , and $R(Q)$ for the radius of the smallest ball that contains Q :

$$r(Q) = \max \{s \mid \exists p \in Q \text{ s.t. } \text{Ball}(p, s) \cap \text{aff}(Q) \subseteq Q\}, \text{ and} \quad (6)$$

$$R(Q) = \min \{s \mid \exists p \in Q \text{ s.t. } \text{Ball}(p, s) \supseteq Q\}, \quad (7)$$

where $\text{Ball}(p, s)$ is the Euclidean ball with center p and radius s .

REDUCED BASES

A lattice $\mathbb{L}(B)$ with dimension $r \geq 2$ has infinitely many bases, and it is well known, that all of them are of the form BU , where U is a unimodular matrix. Multiplying B by a unimodular matrix is equivalent to performing a sequence of three elementary column operations on B : multiplying a column by -1 ; exchanging two columns; and adding an integer multiple of a column to another.

As a lattice may not have an orthonormal basis of unit vectors, we will be interested

in bases comprising “reasonably” short and “near orthogonal” ones. These bases will be called *reduced*.

Example 2. Consider the lattice generated by the vectors

$$b_1 = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad b_2 = \begin{pmatrix} 1/2 \\ \sqrt{3}/2 \end{pmatrix}. \quad (8)$$

Multiplying the matrix $[b_1, b_2]$ with

$$U = - \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$$

gives another basis

$$b'_1 = -2b_1 - b_2, \quad b'_2 = -b_1 - b_2.$$

Figure 2 shows the lattice points, and the two bases, with the vectors in the first clearly shorter, and closer to being orthogonal.

We describe lattice bases that are reduced in the sense of Lenstra, Lenstra, and Lovász (LLL), and Korkin and Zolotarev (KZ). We will say that $b_1, \dots, b_r$ is an LLL (KZ) reduced basis, if it is such a basis of $\mathbb{L}(b_1, \dots, b_r)$.

Figure 2. A lattice, with a reduced, and a nonreduced basis.

Given $b_1, \dots, b_r \in \mathbb{R}^n$, the vectors $b_1^*, \dots, b_r^*$ form their *Gram–Schmidt orthogonalization*, if

$$b_1^* = b_1 \quad (9)$$

$$b_i^* = b_i - \sum_{j=1}^{i-1} \mu_{ij} b_j^* \quad (i = 2, \dots, r), \quad (10)$$

with

$$\mu_{ij} = \langle b_i, b_j^* \rangle / \|b_j^*\|^2 \quad (i = 2, \dots, r; j = 1, \dots, i-1). \quad (11)$$

In other words, b_i^* is the projection of b_i onto the orthogonal complement of the linear span of $b_1, \dots, b_{i-1}$. Given $b_1, \dots, b_r$, their Gram–Schmidt vectors are by definition orthogonal, and will be used as reference vectors to express *near* orthogonality of the b_i .

Convention. Given $b_1, \dots, b_r$, we will write $b_1^*, \dots, b_r^*$ for their Gram–Schmidt vectors, and μ_{ij} for the corresponding coefficients without explicitly saying.

Perhaps the best-known reducedness concept in lattices is LLL reducedness. These bases were introduced by Lenstra and colleagues in their seminal 1982 article [14]. They are polynomial time computable when the lattice is generated by rational vectors, and they found uses in numerous contexts other than integer programming, for instance, in number theory and cryptography. For efficient implementations we refer the reader to the LiDia library [15] at the University of Darmstadt, and the NTL library of Victor Shoup [16].

We use Schrijver’s definition [13], which is less restrictive than the classical one [14].

Definition 1. We say that $b_1, \dots, b_r$ is LLL reduced, if

1. $|\mu_{ij}| \leq 1/2$ ($i = 2, \dots, r; j = 1, \dots, i-1$).
2. $\|b_i^*\| \leq \sqrt{2} \|b_{i+1}^*\|$ ($i = 1, \dots, r-1$).

We remark that an LLL reduced basis remains computable in polynomial time, if we replace the factor of $\sqrt{2}$ with $\sqrt{4/3 + \epsilon}$ for an arbitrarily small positive ϵ : the running time is polynomial in the size of the basis and $1/\epsilon$.

Both conditions in Definition 1 naturally correspond to “near orthogonality,” since in an orthogonal basis all μ_{ij} would be zero, and condition (2) could be achieved by a simple rearranging, with the factor $\sqrt{2}$ replaced by 1. On the other hand, it is easy to construct examples of bases having near parallel vectors that violate conditions 1 and 2 by an arbitrary amount.

Exercise 2. Verify that the lattice in Example 2 does not have an orthogonal basis. Show that b_1 and b_2 form an LLL reduced basis, but b'_1 and b'_2 do not.

From the two basic properties of LLL reduced bases, one can derive several other inequalities that show the shortness (which is less straightforward from conditions (1) and (2) of Definition 1), and near orthogonality of the basis vectors. For details we refer to Lenstra *et al.* [14], and we recall an inequality that will be used in the section titled “Reformulation Methods”.

Proposition 1. Let $b_1, \dots, b_r$ be an LLL reduced basis of the lattice L , and $x_1, \dots, x_t$ be arbitrary linearly independent vectors in L . Then

$$\max \{ \|b_1\|, \dots, \|b_t\| \} \leq 2^{(r-1)/2} \max \{ \|x_1\|, \dots, \|x_t\| \}. \quad (12)$$

We remark, that the performance of LLL reduction in practice is much better than predicted by the estimate (12), especially when t is small.

Korkin–Zolotarev (KZ) reduced bases were introduced by Kannan [2,3] as a key ingredient in his integer programming algorithm, and he also showed that they are computable in polynomial time, when the dimension is fixed. It is currently not known, whether they are computable in polynomial time for varying r . Surprisingly, it turned out that KZ reduced bases have been described previously already in the 19th century [17]; however, no algorithms were known to compute them until Kannan’s result. The LiDia [15] and NTL libraries [16]

also contain efficient subroutines to compute KZ reduced bases.

Definition 2. We say that $b_1, \dots, b_r$ is a KZ reduced basis, if

1. b_1 is a shortest vector of $\mathbb{L}(b_1, \dots, b_r)$;
2. $|\mu_{ij}| \leq 1/2$ ($i = 2, \dots, r; j = 1, \dots, i-1$); and
3. letting $b'_2, \dots, b'_r$ be the projection of $b_2, \dots, b_r$ on the orthogonal complement of the line spanned by b_1 , they form a KZ reduced basis.

While KZ reduced bases are harder to compute than LLL reduced ones, they have stronger properties. We recall two inequalities that we will use later.

Proposition 2. Let $b_1, \dots, b_r$ be a KZ reduced basis of the lattice L , and $x_1, \dots, x_t$ arbitrary linearly independent vectors in L . Then

$$\begin{aligned} \max \{ \|b_1\|, \dots, \|b_t\| \} \\ \leq \frac{\sqrt{t+3}}{2} \max \{ \|x_1\|, \dots, \|x_t\| \}. \end{aligned} \quad (13)$$

Furthermore, for all $j \leq r$

$$\|b_j^*\| \leq \sqrt{r-j+1} \left(\|b_j^*\| \dots \|b_r^*\| \right)^{1/(r-j+1)} \quad (14)$$

holds.

The inequality (13) is due to Lagarias *et al.* [18]. To put into context, we can compare the sublinear factor in it with the exponential factor in (12).

Inequality (14) follows from the definition of KZ reducedness, and for the proof we refer to Kannan [3]. Let us note that multiplying the inequalities $\|b_j^*\| \leq \sqrt{2}^i \|b_{j+i}^*\|$ for $i = 0, \dots, r-j$ in an LLL reduced basis would give a similar inequality with a factor of $2^{(r-j)/4}$ only (or with a factor $(4/3 + \epsilon)^{(r-j)/4}$, if we use a strengthened definition of LLL reducedness); so a KZ reduced basis improves inequality (2) in Definition 1 in an

aggregate sense. Exercise 3 shows that the improvement also holds for every i .

Exercise 3. Show that if $b_1, \dots, b_r$ is a KZ reduced basis, then

$$\|b_i^*\| \leq \sqrt{4/3} \|b_{i+1}^*\| \quad (i = 1, \dots, r-1)$$

holds; so a KZ reduced basis is also LLL reduced.

THE GEOMETRY OF LATTICES AND CONVEX SETS

Proposition 3 concerns the solvability of $(\text{IP}_{B,Q})$, and we will use it in the analysis of both the classical, and the reformulation methods. It asserts that if Q is “large” with respect to the norms of the columns of B , then $(\text{IP}_{B,Q})$ is feasible, and if it is “small,” then one can reduce $(\text{IP}_{B,Q})$ to a “small” number of $r-1$ dimensional subproblems.

Proposition 3. Denote the columns of B by $b_1, \dots, b_r$. Then

1. if Q is contained in the linear span of $\{b_1, \dots, b_r\}$, and

$$r(Q) \geq \frac{1}{2} \sqrt{\|b_1^*\|^2 + \dots + \|b_r^*\|^2}, \quad (15)$$

then $(\text{IP}_{B,Q})$ is feasible.

2. If $(\text{IP}_{B,Q})$ is feasible, then y_r must belong to an interval of length at most

$$\left\lfloor \frac{2R(Q)}{\|b_r^*\|} \right\rfloor + 1; \quad (16)$$

hence $(\text{IP}_{B,Q})$ can be reduced to at most this many $r-1$ -dimensional IP feasibility problems.

For a proof of statement 1 of Proposition 3, we refer to Lenstra [1] (Lemma on p. 540). In fact, Lenstra only states the bound with b_i in place of the b_i^* , but his proof does imply the stronger statement. As motivation, consider a lattice in $\mathbb{R}^2$ spanned by orthogonal vectors, that is, $b_i^* = b_i$ for $i = 1, 2$. The point on the plane, which is farthest from the lattice points is at the intersection of diagonals of

Figure 3. Illustration of statement 2 in Proposition 3.

a grid rectangle, with distance equal to the right-hand side of (15). Thus, a ball around any point in space with this radius will contain a lattice point.

Statement 2 of Proposition 3 is also essentially due to Lenstra, though it is not stated precisely in this form. A geometric proof can be found in Lenstra [1] (p. 541). For motivation, consider Fig. 3. The problem of finding a lattice point in Q is reduced to finding such a point in one of the Q_i , and the distance between the lines containing the Q_i is $\|b_2^*\|$, leading to the desired upper bound. Note that $\|b_2^*\|$ in this example is considerably smaller than $\|b_2\|$.

We give an algebraic proof of statement 2 of Proposition 3. Writing

$$B^{-1}Q = \{y \mid By \in Q\} \quad (17)$$

we show

$$\text{width}(e_r, B^{-1}Q) \leq \frac{2R(Q)}{\|b_r^*\|}. \quad (18)$$

Let $y_{r,1}$ and $y_{r,2}$ denote the maximum and the minimum of y_r over $B^{-1}Q$. Writing $\bar{B}$ for the matrix composed of the first $r-1$ columns of B , and b_r for the last column, it holds that there are $y_1, y_2 \in \mathbb{R}^{r-1}$ such that $\bar{B}y_1 + b_r y_{r,1}$

and $\bar{B}y_2 + b_r y_{r,2}$ are in Q . So,

$$\begin{aligned} 2R(Q) &\geq \|(\bar{B}y_1 + b_r y_{r,1}) - (\bar{B}y_2 + b_r y_{r,2})\| \\ &= \|\bar{B}(y_1 - y_2) + b_r(y_{r,1} - y_{r,2})\| \\ &\geq \|b_r^*\| |y_{r,1} - y_{r,2}| \\ &= \|b_r^*\| \text{width}(e_r, B^{-1}Q) \end{aligned}$$

holds, as required.

Remark 1. If y_r is fixed to an integer k in $(\text{IP}_{B,Q})$, then the corresponding lower-dimensional subproblem is

$$\text{Find } \bar{y} \in \mathbb{Z}^{r-1} : \bar{B}\bar{y} + kb_r \in Q \cap \{y \mid y_r = k\}. \quad (19)$$

Corollary 1. When in $(\text{IP}_{B,Q})$ we branch on $y_r, y_{r-1}, \dots, y_j$ in this order, the number of resulting subproblems on the level of y_j is at most

$$\prod_{i=j}^r \left(\left\lfloor \frac{2R(Q)}{\|b_i^*\|} \right\rfloor + 1 \right). \quad (20)$$

Proof. The formula (19) shows the form of the resulting subproblems, after we

branched on y_r . Using part (2) in Proposition 3 implies that branching on y_{r-1} will create at most

$$\left\lceil \frac{2R(Q)}{\|b_{r-1}^*\|} \right\rceil + 1 \quad (21)$$

subproblems from each of these, and so on, and this completes the proof.

LENSTRA'S AND KANNAN'S ALGORITHMS

Lenstra's Algorithm

Lenstra's paper [1] first disposes with two technicalities. Assuming that P is described as $P = \{x \mid Ax \leq b\}$, with A and b integral, and their components bounded by a in absolute value, Lenstra shows that when (IP) is feasible, it has a solution $\bar{x}$ with $\max_i |\bar{x}_i| \leq (n+1)n^{n/2}a^n$. So we can assume that P is bounded, and Lenstra shows that we can also assume that it is full dimensional.

Next we “round” P by computing in polynomial time an invertible transformation τ , so that

$$R(\tau P)/r(\tau P) \leq c_n := n(n+1) \quad (22)$$

will hold, that is, τP appears relatively “spherical.”

Example 1 (continued). Using Lenstra's algorithm we computed τP , where P is the polyhedron in Example 1. With τ having a transformation matrix

$$\begin{pmatrix} 0.3326 & 0.3101 \\ 0 & 0.0164 \end{pmatrix}, \quad (23)$$

the rounded polyhedron is

$$\begin{aligned} 460 &\leq 153.3333x_1 + 88.5270x_2 \leq 489 \\ 0 &\leq 3.0065x_1 - 56.8034x_2 \leq 10 \\ 0 &\leq 60.9285x_2 \leq 10, \end{aligned} \quad (24)$$

shown in Fig. 4 with the points of the lattice $\tau\mathbb{Z}^2$.

Now (IP) is transformed into trying to find $x \in \tau\mathbb{Z}^n \cap \tau P$. After choosing an LLL reduced basis B for the lattice $\tau\mathbb{Z}^n$, the task becomes

$$\text{Find } y \in \mathbb{Z}^n : By \in \tau P. \quad (\text{IP}_{B,\tau P})$$

Let us write $R := R(\tau P)$, $r := r(\tau P)$, and let $b_1, \dots, b_n$ denote the columns of B . For better intuition, we first describe the algorithm assuming $R = r$ (i.e., that τP is a ball), and that the b_i^* all have the same norm.

By Proposition 3 if

$$r \geq \sqrt{n}\|b_n^*\|/2, \quad (25)$$

Figure 4. The polyhedron of Example 1 after Lenstra's rounding, and the points of τF^2 .

then $(\text{IP}_{B,\tau P})$ is feasible, and if (25) fails, $(\text{IP}_{B,\tau P})$ can be reduced to at most

$$\left\lfloor \frac{2r}{\|b_n^*\|} \right\rfloor + 1 \leq \sqrt{n} + 1$$

$n - 1$ -dimensional subproblems. On the subproblems we apply the algorithm recursively, by making the underlying polyhedra full dimensional, rounded, and finding a new LLL reduced basis for each one. If we denote by $f(n)$ the number of polyhedra that Lenstra's algorithm must examine, we obtain

$$f(n) \leq (\sqrt{n} + 1)f(n - 1); \quad (26)$$

thus, $f(n) = O(n^{n/2})$. The number of arithmetic operations performed on each polyhedron is polynomial, so the overall complexity is polynomial, when n is fixed.

The roundedness of τP , and the reducedness of B make sure that our unrealistic assumption is not far from the truth. Let j be the index such that $\|b_j^*\|$ is maximal, and consider the two cases:

Case 1.

$$r \geq \frac{1}{2}\sqrt{n}\|b_j^*\|.$$

Then the first statement in Proposition 3 shows that $(\text{IP}_{B,\tau P})$ is feasible.

Case 2.

$$r < \frac{1}{2}\sqrt{n}\|b_j^*\|.$$

Then

$$R < \frac{1}{2}c_n\sqrt{n}\|b_j^*\| < \frac{1}{2}c_n\sqrt{n}\|b_n^*\|2^{(n-j)/2},$$

with the first inequality from (22), and the second from the LLL reducedness of B . Then Proposition 3 implies that branching on y_n in $(\text{IP}_{B,\tau P})$ creates at most

$$\left\lfloor \frac{2R}{\|b_n^*\|} \right\rfloor + 1 = O(2^n) \quad (27)$$

subproblems.

Denoting by $f_L(n)$ the number of polyhedra that must be examined by Lenstra's algorithm, we have

$$f_L(n) = O(2^n)f_L(n - 1) = O(2^{n^2}), \quad (28)$$

and the previous argument shows polynomiality of the method for fixed n .

Exercise 4. Verify that if P is the polyhedron in Example 1, and τ is given in (23), then τP indeed has the description given in (24), and $R(\tau P)/r(\tau P) \leq 3.82$.

In contrast, show that the long and thin nature of P is also shown by the poor ratio of $R(P)$ and $r(P)$, namely $R(P)/r(P) \geq 33$.

Kannan's Algorithm

In Kannan's algorithm the setup of making P bounded, full dimensional, and rounded is the same as in Lenstra's method; then a reduced basis for the lattice $\tau\mathbb{Z}^n$ is found. Hence (IP) is again transformed into $(\text{IP}_{B,\tau P})$, and the handling of Case 1 is identical. However, Kannan uses a Korkin–Zolotarev reduced basis for $\mathbb{L}(B)$ in $(\text{IP}_{B,\tau P})$, and again letting j to be the index for which the norm of the corresponding Gram–Schmidt vector is maximal, we enumerate all possible values for $y_j, \dots, y_n$. So, if $j = n$, Kannan's algorithm behaves like Lenstra's, and if $j = 1$, it does complete enumeration.

The complexity analysis of Kannan's algorithm is more technical than Lenstra's, so we only outline a proof showing that it needs to look at only $O(n^{3n})$ polyhedra, as opposed to Lenstra's $O(2^{n^2})$. We first describe Case 2 in detail.

Case 2.

$$r < \frac{1}{2}\sqrt{n}\|b_j^*\|,$$

that is

$$R < \frac{1}{2}c_n\sqrt{n}\|b_j^*\|.$$

Corollary 1 implies that branching on $y_n, \dots, y_j$ creates at most

$$\prod_{i=j}^n \left(\left\lfloor \frac{2R}{\|b_i^*\|} \right\rfloor + 1 \right).$$

subproblems. Using the fact that b_j^* has the largest norm among the Gram–Schmidt vectors, simple manipulation shows that this upper bound is at most

$$(c_n \sqrt{n} + 1)^{n-j+1} \frac{\|b_j^*\|^{n-j+1}}{\|b_j^*\| \cdots \|b_n^*\|}.$$

We now use the KZ reducedness of the b_i , and plug the estimate (14) into the latter expression. Hence the number of subproblems is at most

$$(c_n \sqrt{n} + 1)^{n-j+1} \left(\sqrt{n-j+1} \right)^{n-j+1},$$

which is $O(n^{3(n-j+1)})$. So, denoting by $f_K(n)$ the number of polyhedra that must be examined by Kannan’s algorithm,

$$f_K(n) = O(n^{3(n-j+1)}) f_K(j-1) = O(n^{3n})$$

holds.

REFORMULATION METHODS

In this section we describe the rangespace and nullspace reformulation methods. It will be convenient to assume that our feasibility problem is given as

$$\begin{pmatrix} \ell_1 \\ \ell_2 \end{pmatrix} \leq \begin{pmatrix} A \\ I \end{pmatrix} x \leq \begin{pmatrix} w_1 \\ w_2 \end{pmatrix} \quad (29)$$

$$x \in \mathbb{Z}^n,$$

where A is an integral m by n matrix. The rangespace reformulation of (29) is

$$\begin{pmatrix} \ell_1 \\ \ell_2 \end{pmatrix} \leq \begin{pmatrix} A \\ I \end{pmatrix} Uy \leq \begin{pmatrix} w_1 \\ w_2 \end{pmatrix} \quad (30)$$

$$y \in \mathbb{Z}^n,$$

where U is a unimodular matrix computed to make the columns of the constraint matrix a reduced basis of the generated lattice. If y is feasible for (30), then Uy is feasible for (29), and if x is feasible for (29), then $U^{-1}x$ is feasible for (30), since U^{-1} is integral. This shows the equivalence of the two problems.

The nullspace reformulation is applicable when $w_1 = \ell_1$. Assuming that the rows of A are linearly independent, it is

$$\ell_2 - x_0 \leq By \leq w_2 - x_0 \quad (31)$$

$$y \in \mathbb{Z}^{n-m},$$

where $x_0 \in \mathbb{Z}^n$ satisfies $Ax_0 = \ell_1$, and B is a reduced basis of $\mathbb{N}(A)$ (recall the definition of the null-lattice from (5)). Since any integral solution of the system $Ax = \ell_1$ can be written as the sum of x_0 , and an element of $\mathbb{N}(A)$, the two formulations are equivalent [13].

For brevity, if the columns of the constraint matrix in (30) form an LLL reduced basis of the generated lattice, we will call (30) the *LLL rangespace reformulation* of (29), and we will similarly talk about the LLL nullspace reformulation, KZ rangespace reformulation, and so on.

Remark 2. In its simplest form, the rangespace reformulation method transforms the feasibility problem

$$Ax \# b, x \in \mathbb{Z}^n$$

into

$$AUy \# b, y \in \mathbb{Z}^n,$$

where U is a unimodular matrix, AU is a reduced basis of the lattice $\mathbb{L}(A)$, and $\#$ denotes an arbitrary mixture of equality and inequality constraints. For the analyses that we present, however, it is convenient to work with a problem in the form of (29).

Also, one can solve an integer programming optimization problem by reducing it to a sequence of feasibility problems, on which a suitable reformulation can be then applied. The simplest direct approach is transforming

$$\max \{cx \mid Ax \# b, x \in \mathbb{Z}^n\}$$

into

$$\max \{cUy \mid AUy \# b, y \in \mathbb{Z}^n\},$$

where again $\#$ is a mixture of equality and inequality constraints, U is a unimodular matrix, and

$$\begin{pmatrix} c \\ A \end{pmatrix} U$$

is a reduced basis of the generated lattice.

Let us note how the reformulated problems fit in the framework of $(IP_{B,Q})$ with the polyhedron Q being simply a box, and B constructed directly from the constraint matrix of (29). This is in contrast with Lenstra's and Kannan's algorithms, where Q is a transformed version of P , and B is a reduced basis of the transformation matrix.

Decomposable Knapsack Problems and Their Reformulations

In this section we are interested in feasibility problems of the type

$$\begin{pmatrix} \ell_1 \\ \ell_2 \end{pmatrix} \leq \begin{pmatrix} a \\ I \end{pmatrix} x \leq \begin{pmatrix} w_1 \\ w_2 \end{pmatrix} \quad (32)$$

$x \in \mathbb{Z}^n,$

with a decomposing as

$$a = \lambda p + r, \quad (33)$$

where a, p , and r are integral row vectors, the components of p relatively prime, and λ is an integer. We will call these *decomposable knapsack problems (DKPs)*, and note that this is not a formal definition, since any knapsack problem with a constraint vector a can be written in this form with $p = a, r = 0$, and $\lambda = 1$. However, in all interesting cases λ will be at least 2, and in most cases relatively large with respect to $\|p\|$ and $\|r\|$.

There are a wide variety of instances, which fit into this framework, with three interesting properties, that we repeat from the introduction:

- (i) they are difficult for ordinary B&B;
- (ii) their infeasibility is proven by branching on px ; and
- (iii) when λ is sufficiently large, branching on the last variable in the reformulations has the same effect as branching on px in the original problem.

Example 1 (continued). This instance fits the mold of (32) with the constraint vector, and its decomposition given by

$$\begin{aligned} a &= (51, 49), & p &= (1, 1), \\ r &= (1, -1), & \lambda &= 50. \end{aligned} \quad (34)$$

The definition of the rest of the data (of ℓ_1, ℓ_2, w_1 , and w_2) is obvious.

With P denoting the underlying polyhedron, we have

$$\begin{aligned} \max \{px \mid x \in P\} &= 489/49 = 9.9796, \\ \min \{px \mid x \in P\} &= 460/51 = 9.0196; \end{aligned} \quad (35)$$

so, branching on px proves the infeasibility of this instance, and it is straightforward to check that the same holds for the generalization of Exercise 1.

The next example is a simplification of Jeroslow's classic problem [7], which established that ordinary B&B may take exponential time even on a trivial problem.

Example 3. Let n be a positive, odd integer. The problem

$$\begin{aligned} 2 \sum_{i=1}^n x_i &= n \\ 0 &\leq x \leq e \\ x &\in \mathbb{Z}^n \end{aligned} \quad (36)$$

is infeasible, and the infeasibility is proven by branching on $\sum_{i=1}^n x_i$. At the same time, ordinary B&B needs to enumerate at least $2^{(n-1)/2}$ nodes to do the same. For a proof of the latter fact we refer to Jeroslow's [7] or Krishnamoorthy and Pataki's paper [5] (p. 247).

This instance also fits into the framework of (32) with

$$a = 2e, \quad p = e, \quad r = 0, \quad \lambda = 2, \quad (37)$$

and $\ell_1 = w_1 = n$.

Another family of instances with similar behavior is related to the famous *Frobenius problem*. For a positive integral vector $a =$

$(a_1, \dots, a_n)$, the *Frobenius number* $\text{Frob}(a)$ is the largest integer for which we cannot make a change using the denominations $a_1, \dots, a_n$; in other words, the largest β for which the integer programming problem

$$\begin{aligned} ax &= \beta \\ x &\geq 0 \\ x &\in \mathbb{Z}^n, \end{aligned} \quad (38)$$

is infeasible. The *Frobenius problem* is computing $\text{Frob}(a)$: for a recent review we refer to a book by Ramirez Alfonsin [19].

The Frobenius problem gives rise to interesting, and difficult integer programming instances. Cornuéjols *et al.* [20] studied knapsack problems with a decomposable structure, and showed how to compute the Frobenius number by solving a sequence of integer programming problems using a test set approach.

Aardal and Lenstra [8,9] considered instances of the form (38), with a decomposing as in (33), and β a positive integer. Following the arguments in Krishnamoorthy and Pataki [5], we give a simplified description of the instances they constructed, and in addition show that they fit Property (ii).

Example 4. Consider a knapsack feasibility problem (38) with a decomposing as in (33), and β a positive integer. We assume that p is componentwise positive, it is not a multiple of r , and

$$q_1 := r_1/p_1 \leq \dots \leq q_n := r_n/p_n. \quad (39)$$

Proposition 4. *Define*

$$\begin{aligned} k &= \lfloor (\lambda + q_1 - 1)/(q_n - q_1) \rfloor - 1, \\ \beta &= \lceil (\lambda + q_n)k \rceil, \end{aligned} \quad (40)$$

and assume that λ is large enough so k and β are both positive. Then the infeasibility of (38) is proven by branching on px .

Proof. Let us consider the interval

$$I = ((\lambda + q_n)k, (\lambda + q_1)(k + 1)), \quad (41)$$

and note that I has length strictly larger than one by the choice of k . Next, let us denote by P the polyhedron of the LP relaxation of (38). Since $a_i = \lambda p_i + r_i$, the ordering in (39) implies

$$a_1/p_1 \geq \dots \geq a_n/p_n, \quad (42)$$

therefore

$$\begin{aligned} \max \{px \mid x \in P\} &= p_1\beta/a_1, \\ \min \{px \mid x \in P\} &= p_n\beta/a_n, \end{aligned} \quad (43)$$

hold. So $\text{iwidth}(p, P) = 0$ holds, when the above maximum and minimum are in the interval $(k, k + 1)$. A simple calculation shows that this happens exactly when $\beta \in I$, which is true because β is the ceiling of the lower end point of I , and $|I| > 1$.

Since (38) is infeasible with a large right-hand side, it is difficult for ordinary B&B, and it is also difficult when the right-hand side is chosen to be $\text{Frob}(a)$.

The following exercises review the recipe from Krishnamoorthy and Pataki [5], and its application to construct Avis's instance from Chvátal [21]:

Exercise 5. Let p and r be arbitrary integral vectors, ℓ_2 and w_2 bound vectors in (32), and k an integer with $0 < k \leq pw_2$. Prove that if we find λ, ℓ_1 , and w_1 to satisfy $\ell_1 \leq w_1$, and

$$\begin{aligned} \max \{rx \mid px \leq k, \ell_2 \leq x \leq w_2\} &+ k\lambda < \ell_1, \\ \text{and} \\ \min \{rx \mid px \geq k + 1, \ell_2 \leq x \leq w_2\} \\ &+ (k + 1)\lambda > w_1, \end{aligned} \quad (44)$$

then the infeasibility of (32) is proven by branching on px .

Show that the instances of Examples 1, 3, and 4 can be obtained this way, with $k = 9$, $k = (n - 1)/2$, and k defined in (40), respectively.

Figure 5. Example 1 after applying the LLL rangespace reformulation.

For a proof of why the above recipe creates hard integer programs, and how the difficulty depends on p, r, λ , and k , we refer to Krishnamoorthy and Pataki [5].

Exercise 6. Using the result of Exercise 5, show that the subset sum problem

$$\begin{aligned} ax &= \beta \\ x &\in \{0, 1\}^n, \end{aligned} \quad (45)$$

where n is odd,

$$\begin{aligned} a &= (n(n+1)+1, \dots, n(n+1)+n), \\ \beta &= \left\lfloor \sum_{i=1}^n a_i/2 \right\rfloor \end{aligned} \quad (46)$$

is infeasible. This instance was proposed by Avis [21], and it is known that ordinary B&B needs at least $2^{(n-1)/2}$ nodes to prove its infeasibility.

Example 1 (continued). To motivate Theorem 1, the main result presented in this section, we computed the LLL rangespace reformulation of Example 1. With

$$U = \begin{pmatrix} -1 & -16 \\ 1 & 17 \end{pmatrix},$$

it is

$$460 \leq 2y_1 + 17y_2 \leq 489$$

$$\begin{aligned} 0 &\leq -y_1 - 16y_2 \leq 10 \\ 0 &\leq y_1 + 17y_2 \leq 10 \\ y_1, y_2 &\in \mathbb{Z}, \end{aligned} \quad (47)$$

shown in Fig. 5. It is interesting to note that the underlying polyhedron is still long and thin, unlike the polyhedron in Fig. 4 produced by the τ transformation in Lenstra's and Kannan's methods, but now infeasibility is proven by branching on y_2 .

Theorem 1. Denote by P the polyhedron of (32), and by Q the polyhedron of its LLL rangespace reformulation. If

$$\lambda > 2^{(n-1)/2}(\|r\| + 1)^2\|p\|, \quad (48)$$

then

$$\begin{aligned} \text{width}(e_n, Q) &= \text{width}(p, P), \text{ and} \\ \text{iwidth}(e_n, Q) &= \text{iwidth}(p, P). \end{aligned} \quad (49)$$

Sketch of proof Let us write

$$A = \begin{pmatrix} a \\ I \end{pmatrix}. \quad (50)$$

First we show that $\mathbb{L}(A)$ has at least $n-1$ vectors with norm bounded by $(\|r\| + 1)\|p\|$.

Indeed, there are $n - 1$ vectors in $\mathbb{N}(p)$ with norm at most $\|p\|$, and if w is such a vector, then

$$\|Aw\| \leq (\|r\| + 1)\|p\|. \quad (51)$$

Next, let U be the unimodular matrix in the LLL rangespace reformulation of (32). Since AU is an LLL reduced basis of $\mathbb{L}(A)$, Proposition 1 shows that its first $n - 1$ columns have norm of at most

$$2^{(n-1)/2}(\|r\| + 1)\|p\|. \quad (52)$$

The integrality of pU , and the choice of λ implies that the first $n - 1$ components of pU are 0, otherwise the corresponding column of AU would have norm larger than as given in (52). For the details we refer to Krishnamoorthy and Pataki [5] (p. 262).

Hence $pU = \delta e_n$ holds for some integer δ , that is, $p = \delta e_n U^{-1}$, and since the components of p are relatively prime, $\delta = \pm 1$.

Finally, the definitions of P and Q imply

$$\max\{px \mid x \in P\} = \max\{pUy \mid y \in Q\}, \quad (53)$$

and the same holds for the minimum. Using $pU = \pm e_n$ with (53), and the definition of width and integer width prove (49).

Remark 3. One can see that an analogous result holds for the KZ rangespace reformulation, even if we replace the lower bound (48) with the weaker

$$\lambda > \sqrt{(n+3)/2}(\|r\| + 1)^2\|p\|. \quad (54)$$

A variant of Theorem 1 about the nullspace reformulation is proven in Krishnamoorthy and Pataki [5].

Remark 4. Another decomposable knapsack instance, similar to Avis's, was described by Todd in Chvátal's 1980 paper [21]. It is interesting that Jeroslow, Avis, and Todd proved that their instances fit property (i), but they did not mention that they fit property (ii) as well.

Aardal and Lenstra [8,9] showed that denoting by b_{n-1} the last column of

the constraint matrix in the nullspace reformulation

$$\|b_{n-1}\| \geq \|b_{n-1}^*\| = \Omega(\lambda)$$

holds, and they argued that $\|b_{n-1}\|$ being long implies that branching on y_{n-1} will generate a small number of subproblems.

Krishnamoorthy and Pataki [5] pointed out a gap in the proof of $\|b_{n-1}^*\| = \Omega(\lambda)$, and constructed an example of a polyhedron $Q = \{y \in \mathbb{R}^r \mid \ell \leq By \leq w\}$, where the columns form an LLL reduced basis of $\mathbb{L}(B)$, but branching on y_r creates $c^r\|b_r\|$ subproblems for some $c > 1$. Furthermore, they proved that the instance of Example 4 fits property (ii).

Analyzing the Reformulation Methods without Assuming Structure

Here we describe an analysis of the reformulation methods based on the paper of Pataki *et al.* [10], without assuming any structure on the matrix A in (29). Interestingly, we will find that ordinary B&B solves the reformulation of the *majority* of the instances *without any branching*. We explain the connection with solving low-density subset sum problems after the proof.

We assume $n \geq 5$, and when a statement is true for all, but at most a fraction of $1/2^n$ of the elements of a set S , we say that it is true for *almost all* elements. For positive integers m, n , and M we denote by $G_{m,n}(M)$ the set of matrices with m rows and n columns, and the entries from $\{1, \dots, M\}$, and by $G'_{m,n}(M)$ the subset of $G_{m,n}(M)$ consisting of matrices with linearly independent rows.

We use a version of ordinary B&B that branches on the variables in reverse order, and call this algorithm *reverse B&B*. If B&B generates at most one node at each level of the tree, we say that it solves an integer feasibility problem *at the root node*. When the system $Ax = \ell_1$ does not have an integral solution, the nullspace reformulation does not exist; for simplicity we still say that in this case the reformulated instance is solved at the root node.

Theorem 2. *If $M \geq (2^{(n+4)/2} \|(w_1; w_2) - (\ell_1; \ell_2)\|)^{n/m+1}$, then for almost all $A \in G_{m,n}(M)$ reverse B&B solves the LLL rangespace reformulation of (29) at the root node.*

Also, if $M \geq (2^{(n-m+4)/2} \|w_2 - \ell_2\|)^{n/m}$, then for almost all $A \in G'_{m,n}(M)$ reverse B&B solves the LLL nullspace reformulation of (29) at the root node.

Proof Sketch We outline a proof of the first statement, and refer the reader to Pataki *et al.* [10] for details, and the proof of the second. For convenience, we shall write $(A; I)$ for the matrix obtained by stacking A on top of I , and the meaning of $(\ell_1; \ell_2)$ and $(w_1; w_2)$ will be analogous.

Let U be the matrix such that the columns of $(A; I)U$ form an LLL reduced basis of the generated lattice. We first use Corollary 3 with $B = (A; I)U$, and $Q = \{y \mid (\ell_1; \ell_2) \leq y \leq (w_1; w_2)\}$ to find that when reverse B&B is applied to (30), the number of B&B nodes on the level of y_j is at most

$$\prod_{i=j}^n \left(\left\lfloor \frac{\|(w_1; w_2) - (\ell_1; \ell_2)\|}{\|b_i^*\|} \right\rfloor + 1 \right),$$

where $b_1^*, \dots, b_n^*$ form the Gram–Schmidt orthogonalization of the columns of $(A; I)U$. Hence if

$$\|b_i^*\| > \|(w_1; w_2) - (\ell_1; \ell_2)\| \quad \forall i = 1, \dots, n, \quad (55)$$

then the problem is solved at the root node.

The definition of LLL reducedness implies

$$\begin{aligned} \|b_i^*\| &\geq \frac{1}{2^{(i-1)/2}} \|b_1\| \\ &\geq \frac{1}{2^{(i-1)/2}} \lambda_1(\mathbb{L}(A; I)), \end{aligned} \quad (56)$$

where $\lambda_1(\mathbb{L}(A; I))$ denotes the length of the shortest nonzero vector in $\mathbb{L}(A; I)$. So (55) holds, when

$$\lambda_1(\mathbb{L}(A; I)) > 2^{(n-1)/2} \|(w_1; w_2) - (\ell_1; \ell_2)\|. \quad (57)$$

Condition (57) does not hold for all A matrices, so let us call a matrix $A \in G_{m,n}(M)$ *bad*, when (57) fails. One can show that for

$r > 0$ the shortest vector in $\mathbb{L}(A; I)$ is strictly longer than r for all, but at most a fraction of

$$\frac{(2\lfloor r \rfloor + 1)^{n+m}}{M^m} \quad (58)$$

matrices in $G_{m,n}(M)$. We refer the reader to Lemma 2.2 in Pataki *et al.* [10] for details.

Using this result, it follows that when M is as given in the first statement of the theorem, the fraction of bad matrices is at most $1/2^n$, and this completes the proof.

Remark 5. A stronger version of Theorem 2 is true, if we use a “more reduced” basis, in particular, a so-called *reciprocal KZ reduced basis*. For details, we refer to Pataki *et al.* [10].

There is an interesting connection with earlier work on subset sum problems, which we outline here. Furst and Kannan [22] based on Lagarias’ and Odlyzko’s [23] and Frieze’s [24] work show that the subset sum problem

$$\begin{aligned} ax &= \beta \\ x &\in \{0, 1\}^n, \end{aligned} \quad (59)$$

is solvable in polynomial time using a simple iterative method for almost all $a \in G_{1,n}(M)$, and all right-hand sides, when M is sufficiently large, and a reduced basis of $\mathbb{N}(a)$ is available. Their bound on M is $2^{n^2/2+2n} n^{3n/2}$, when the basis is LLL reduced, and $2^{(3/2)n \log n + 5n}$, when it is reciprocal KZ reduced.

Subset sum problems with potentially such large coefficients find uses in cryptography. The vector a is a public key, x is a message, and the encoded message that the sender transmits is ax . The wide range of the coefficients of a makes sure that few right-hand sides among the integers in $\{1, \dots, \sum_{i=1}^n a_i\}$ arise as ax for some $x \in \{0, 1\}^n$, and it is rare for two distinct x vectors to map to the same ax . The results of Lagarias and Odlyzko [23], Frieze [24], and a later improvement by Coster *et al.* [25] show that using basis reduction the solution of (59) can be found with high probability, if it is known to exist. In other words, an intercepted message can be decoded for most

of the a public keys. Furst and Kannan [22] go further by finding the solution if it exists, and a proof of infeasibility for instances that do not have a solution.

Our bounds obtained by letting $m = 1$ in Theorem 2 and its variant that uses reciprocal KZ reducedness are comparable to Furst and Kannan's bounds, when the size of M , that is, $\lceil \log(M + 1) \rceil$ is concerned. Precisely, the bound on the size of M is $O(n^2)$, when we use an LLL reduced basis, and $O(n \log n)$, when we use a reciprocal KZ reduced basis.

So these results generalize the solvability results of [22] from subset sum problems to bounded integer programs. It is also interesting that one can prove complexity results via branch-and-bound, an algorithm that has been considered inefficient from the theoretical point of view.

FURTHER READING AND COMPUTATIONAL TESTING

In this section we briefly review results on integer programming in fixed dimension, whose detailed treatment is beyond the scope of our survey, mention other surveys that the reader may find to be of interest, and review computational experience with lattice-based methods. We will write “polynomial time when the dimension is fixed” as *fd-polynomial time* for short.

The generalized basis reduction algorithm of Lovász and Scarf [26] also solves (IP) in *fd-polynomial time*. Instead of rounding the underlying polytope, like Lenstra's and Kannan's algorithms do, at its core is a subroutine that finds an integral vector p such that $\text{width}(p, P)$ is relatively small, by solving a sequence of linear programs. This vector is then used for branching. Kannan [27] presented an algorithm to solve the Frobenius problem in *fd-polynomial time*.

An *fd-polynomial time* algorithm exists even to *count* the number of feasible solutions of (IP). The breakthrough algorithm to achieve this is due to Barvinok [28]. His algorithm was considerably simplified by Dyer and Kannan [29], and successfully implemented by De Loera *et al.* [30]. Koeppel [31]

developed, and implemented a newer primal variant, which in many cases is also faster in practice.

Given $c \in \mathbb{Z}^n$, the integer optimization problem is finding a feasible solution of (IP), which maximizes cx . One can solve this problem by reducing it to a sequence of feasibility problems; however, it is interesting to study direct approaches, which are theoretically efficient. We refer to Eisenbrand [32] for a fast algorithm to solve this problem, under the assumption that the number of variables, and the number of constraints are both fixed. Computing the *integer programming gap* is the problem of finding the maximum difference between the optimal value of an integer programming problem, and its LP relaxation, as the right-hand side varies. An *fd-polynomial time* algorithm for this problem was developed by Hoşten and Sturmfels [33], assuming that the number of constraints is also fixed. Eisenbrand and Shmonin [34] described an *fd-polynomial* algorithm even when the number of constraints is allowed to vary.

Other reviews on the uses of basis reduction and integer programming that the reader may find useful are by Kannan [35], Aardal and Eisenbrand [36], and Eisenbrand [37]: the latter is also a tutorial, with accompanying exercises. A substantial part of the books of Schrijver [13], and Grötschel *et al.* [38] are also devoted to this subject.

There is surprisingly little experience with implementing Lenstra's algorithm. Gao and Zhang [39] described an implementation, and Mehrotra and Li [6] presented and implemented a nonrecursive variant, in which branching is done on a hyperplane in the original formulation. Cook *et al.* [40] reported a successful implementation of the generalized basis reduction method.

There is more computational evidence of the effectiveness of the reformulation methods.

Aardal *et al.* [4] successfully tested their reformulation on knapsack-type feasibility problems that arise from circuit design. Another application of lattice-based methods is on the *marketshare* problems of Cornuéjols and Dawande [41]. Suppose that a company supplies n retailers with m products, with

retailer j receiving a_{ij} units of product i . The company has two divisions. We would like to assign each retailer to one of the divisions, so the retailers in each division receive approximately half of the total supply of each product.

Letting A be a matrix with the (i, j) th entry equal to a_{ij} , and $b \in \mathbb{Z}^m$ with the i th entry equal to

$$\left\lfloor \frac{1}{2} \sum_{j=1}^n a_{ij} \right\rfloor,$$

the problem can be formulated as

$$\begin{aligned} Ax &= b \\ x &\in \{0, 1\}^n, \end{aligned} \quad (60)$$

where x_j is set to 1, if retailer j is assigned to division 1, and 0 otherwise.

Two variants of (60) have also been studied, which are especially interesting, when the original problem is infeasible. The first is an optimization version introduced in Cornuéjols and Dawande [41], which attempts to minimize $\|Ax - b\|_1$. The second is a relaxed version studied in Pataki *et al.* [10], namely,

$$\begin{aligned} b - e &\leq Ax \leq b \\ x &\in \{0, 1\}^n. \end{aligned} \quad (61)$$

This formulation attempts to find a near equal market split (of course if $\sum_{j=1}^n a_{ij}$ is odd, then the i th constraints in (61) are as good as the i th constraint in (60)).

The marketshare problems are exceptionally difficult to solve by commercial integer programming software, and Cornuéjols and Dawande offered them as a challenge to the Integer Programming community. They generated the a_{ij} uniformly at random in the interval $\{1, \dots, 100\}$, with the choice $n = 10(m - 1)$. Aardal *et al.* [42] showed that by using the CPLEX 6.5 commercial Mixed Integer Programming (MIP) solver, the nullspace reformulations of 7×60 instances were solved in a reasonable amount of time, whereas the original formulations of even 5×60 instances could not be handled. Improved results were obtained for the optimization versions as well, and the

authors also derived an approximation for the number of feasible solutions of (60) in terms of m and n . A generalization of the marketshare problem with a matrix variables, and two-sided constraints was studied by Louveaux and Wolsey [43].

A counterintuitive guess based on Theorem 2 is that the reformulations of the marketshare problems should become *easier* in practice, when the a_{ij} are drawn from $\{1, \dots, M\}$, and M grows. This was confirmed by computational experiments by Pataki *et al.* [10]. For instance, the average number of nodes over 12 instances that needed to be enumerated by CPLEX 9 to solve the rangespace reformulation of 5×40 relaxed instances with $M = 100$ was 38865. However, the average number of nodes with $M = 10000$ was just 1976.

A computational study on the Frobenius instances given in Example 4 was carried out by Aardal and Lenstra [8]. Krishnamoorthy and Pataki [5] experimented with more general DKPs, both with feasible and infeasible instances, and using varying bounds. As expected, the reformulations were quite easy to solve, usually requiring less than a hundred nodes, even when λ was not large enough for Theorem 1 (or its version using KZ reducedness) to give theoretical guarantees.

Two other interesting observations were made in Krishnamoorthy and Pataki [5]: first, when the knapsack problem has an equality constraint, and so both reformulations were applicable, there was no difference in their performance. Second, Theorem 1, which asserts that branching on a single variable in the reformulation is equivalent to branching on px in the original problem is verified by another experiment: creating a new variable z , and adding the redundant constraint $z = px$ to the original formulations. Even without specifying a higher priority for branching on the z variable, the *original* instances with this addition solved as fast as the reformulations.

BATCH ARRIVALS AND SERVICE—SINGLE STATION QUEUES

Texas Tech University, Lubbock, Texas

INTRODUCTION

Queueing models exhibiting arrival and/or service patterns in batches or groups are commonly classified as bulk queueing models. The earliest studies on batch queueing models were applied to the patient appointment scheduling problem, in which the steady-state queue length distribution was characterized and obtained [1,2]. More recent applications of bulk queueing models include computer high-speed random access networks [3], data packet switching [4], Very Large Scale Integrated (VLSI) circuits [5,6], manufacturing systems [7], and transportation systems [8–10], among several others. Unlike the analysis of traditional queueing models, the study of bulk queues is not straightforward.

In traditional queueing analysis, it is often assumed that customers arrive singly; however, this assumption seems invalid in several real-world applications as customers often arrive in batches. A simple example of *batch arrival* queues includes packages arriving by courier truck at a sorting facility, pallets arriving at a retail warehouse, and so on. Note that in these examples, arrivals do not come singly, but rather in bulk or batches where the size of the batch can be a fixed constant or a random variable. In other instances, customers may arrive singly to a server, but are subsequently served in

batches of a fixed or random size. Examples of such *batch service* queues include vehicles waiting at a traffic light, people in an elevator, passengers in an airplane, and so on.

The analysis of a single-server *bulk service* queue, where customers are served in batches of size k , has three variations: (i) a *full batch* model; (ii) a *partial batch* model, in which customers can join the server while it is in process until a full batch is reached; and (iii) a *Partial Batch* model, in which late arriving customers are not permitted to join the server directly. In a full batch model, the service begins only when k customers are present in the queue; that is, when less than k customers are present, the server waits until k customers have joined the queue and then processes all customers simultaneously. A simple example of a full batch model includes forklift operations, in which only complete pallets are transported that are built-up over time. In a partial batch model, service begins on the batch whether or not k are present once the server becomes free. In type (ii) partial batch model, new arrivals are permitted to join the batch of ongoing service until the threshold k is reached, and in type (iii) new arrivals have to wait until next time when the server is available. Note that, in a partial batch model, the service time is congruent to a complete batch, whether or not it is actually full. A simple example of partial batch model of type (ii) is a guided tour, in which late arriving customers are permitted to join the tour up to the threshold k and finish the tour as a group. An example of type (iii) partial batch model where late arriving passengers are not permitted to join the airplane. Although partial batch models of type (iii) are found in several real-life examples, they present inherent challenge and modeling difficulties. In this article, we do not consider the modeling and analysis of type (iii) partial batch model. In the next section, we present single-server batch models with Markovian arrivals and services, and extensions to general distribution.

SIMPLE BULK MODELS

Single-Server Markovian Batch Arrival Model:
 $M^{[X]}/M/1$

In this section, we study a single-server Markovian bulk arrival queue through the treatment of a simple $M/M/1$ queue as a modified birth–death process. Let us assume the arrival stream occurs in batches of size X , which denotes a random variable of nonnegative values with probability distribution $b_k = \Pr\{X = k\}$, $k \geq 1$. The arrival stream constitutes a compound Poisson process with an average arrival rate λ , and services are performed one at a time according to an exponential distribution with rate μ . Let $N(t)$ denote the number of customers in the system at time t , and P_n denote the probability that there are n customers in the system at time t given by $P_n(t) = \Pr\{N(t) = n\}$, $n \geq 0$. The state space of the system increases by nonunitary values based on the arriving group size and decreases by one with a service completion, it follows that $\{N(t)\}$ forms a modified birth–death process with steady-state balance equations given by

$$\begin{aligned} \lambda P_0 - \mu P_1 &= 0 \\ (\lambda + \mu)P_n - \lambda \sum_{k=1}^n b_k P_{n-k} - \mu P_{n+1} &= 0, \\ \text{for } n \geq 1 \end{aligned}$$

where $P_n = \lim_{z \rightarrow 1} P_n(z)$. To solve these equations, we employ probability generating functions denoted by $P(z)$ for the steady-state probabilities and $B(z)$ for the batch size probabilities, defined by

$$P(z) = \sum_{n=0}^{\infty} P_n z^n$$

and

$$B(z) = \sum_{k=1}^{\infty} b_k z^k \quad \text{with } |z| \leq 1. \quad (1)$$

Multiplying the balance equations by suitable powers of z , interchanging the summations, and simplifying the expressions give

$$\begin{aligned} (\lambda + \mu)P(z) - \mu P_0 - \lambda \sum_{k=1}^{\infty} b_k z^k \sum_{n=k}^{\infty} P_{n-k} z^{n-k} \\ - \mu \sum_{n=0}^{\infty} P_{n+1} z^n = 0. \end{aligned} \quad (2)$$

The middle term in the above equation is merely a convolution of discrete random variables representing the product of steady-state probabilities and batch size probabilities, that is

$$\begin{aligned} B(z)P(z) &= \sum_{k=1}^{\infty} b_k z^k \sum_{n=k}^{\infty} P_{n-k} z^{n-k} \\ &= \sum_{n=1}^{\infty} \sum_{k=1}^n P_{n-k} b_k z^n. \end{aligned}$$

Further simplification of Equation (1) gives $P(z)$ in terms of the batch size probabilities $B(z)$ and P_0 , from whence

$$\begin{aligned} (\lambda + \mu)P(z) - \mu P_0 - \lambda B(z)P(z) \\ - \frac{\mu}{z} \sum_{m=1}^{\infty} P_m z^m = 0 \\ (\lambda + \mu)P(z) - \mu P_0 - \lambda B(z)P(z) \\ - \frac{\mu}{z} [P(z) - P_0] = 0 \\ P(z) = \frac{\mu P_0 (1 - z)}{\mu (1 - z) - \lambda z [1 - B(z)]} \\ \text{with } |z| \leq 1. \end{aligned} \quad (3)$$

To obtain P_0 , we use the normalizing condition $\sum_n P_n = 1$, from whence $\lim_{z \rightarrow 1} P(z) = 1$ yielding the expression

$$P_0 = 1 - \frac{\lambda B'(1)}{\mu} = 1 - \rho,$$

where $B'(1) = \lim_{z \rightarrow 1} \sum_{k=1}^{\infty} k b_k z^{k-1} = E(X) = b$ is the average batch size, and the corresponding traffic intensity based on the average batch size “ b ” is given by $\rho = \frac{\lambda b}{\mu}$. Substituting P_0 into $P(z)$ gives the expression

$$\begin{aligned} P(z) &= \frac{\mu (1 - \rho) (1 - z)}{\mu (1 - z) - \lambda z [1 - B(z)]} \\ &\quad \text{with } |z| \leq 1. \end{aligned} \quad (4)$$

Inverting the probability generating function to obtain P_n is analytically cumbersome, yet numerical methods can be employed to evaluate the system probabilities for a specified batch size distribution. Two special cases of either a constant or geometric batch size distribution are discussed in Gross *et al.* [11, pp. 120–121]. Obtaining the mean and variance of the number of customers in the system, however, is rather straightforward through the application of L' Hospital's rule, since the expression for $P(z)$ contains $(1 - z)$ in the numerator and $(1 - B(z))$ in the denominator. Therefore, the mean number of customers in the system at steady state is given by

$$\begin{aligned} E[N] &= \lim_{z \rightarrow 1} P'(z) = \frac{2\rho + \frac{\lambda}{\mu} B''(1)}{2(1 - \rho)} \\ &= \frac{\rho + \frac{\lambda}{\mu} E[X^2]}{2(1 - \rho)}, \end{aligned} \quad (5)$$

as the average batch size is b and $B''(1) = E[X^2] - E[X]^2$. Similarly, the variance of the number of customers in the system at steady state can be obtained after the repeated application of L' Hospital rule by evaluating $\lim_{z \rightarrow 1} P''(z)$.

Single-Server Markovian Batch Service Model: $M/M^{[X]}/1$

The single-server batch service queue assumes a unity Poisson arrival process with rate λ , and exponentially distributed service times with rate μ for batches of size X . As noted previously, there are two variations of a batch service model, that is, (i) *full batch* case, models where the server waits until exactly k customers are present in the system before processing; and (ii) *partial batch* case, models where the server can start servicing when fewer than k customers are present in the system, thereby permitting all new arrivals to go directly into service until the threshold of k customers is reached. In either case, customers depart as a batch, either full or partial, at a service completion epoch, not singly. Interestingly, depending on the assumption of case (i) or (ii) leads to very different results for the model while

preserving common modeling techniques used to analyze the model. For analysis and results on case (ii) *partial batch* service models, the readers are referred to Gross *et al.* [11, pp. 124]. In the analysis presented here, however, we restrict our attention to case (i) *full batch* service models that are more common in practice.

Let the number of customers in the system be denoted by $\{P_n, n \geq 0\}$, for which the steady-state balance equations of the full service batch model is given by

$$\begin{aligned} \lambda P_0 - \mu P_k &= 0 \\ \lambda P_n - \lambda P_{n-1} - \mu P_{n+k} &= 0 \quad \text{for } 1 \leq n \leq k \\ (\lambda + \mu) P_n - \lambda P_{n-1} - \mu P_{n+k} &= 0 \quad \text{for } n \geq k. \end{aligned} \quad (6)$$

Multiplying the above equations with suitable powers of z , and employing the probability generating functions defined in Equation (1) yield the expression

$$\begin{aligned} \lambda P_0 + \lambda \sum_{n=1}^{k-1} P_n z^n + (\lambda + \mu) \sum_{n=k}^{\infty} P_n z^n - \mu P_k \\ - \lambda \sum_{n=1}^{k-1} P_{n-1} z^n - \mu \sum_{n=1}^{k-1} P_{n+k} z^n - \lambda \sum_{n=k}^{\infty} P_{n-1} z^n \\ - \mu \sum_{n=k}^{\infty} P_{n+k} z^n = 0. \end{aligned}$$

Simplifying further and multiplying with z^k yields

$$\begin{aligned} \left[(\lambda + \mu) z^k - \lambda z^{k+1} - \mu \right] P(z) \\ - \mu \left(z^k - 1 \right) \sum_{n=0}^{k-1} P_n z^n = 0. \end{aligned} \quad (7)$$

Rearranging these terms yields the probability generating function

$$\begin{aligned} P(z) &= \frac{(1 - z^k) \sum_{n=0}^{k-1} P_n z^n}{1 + \left(\frac{\lambda}{\mu} \right) z^{k+1} - \left(1 + \frac{\lambda}{\mu} \right) z^k} \\ &\quad \text{with } |z| \leq 1. \end{aligned} \quad (8)$$

To solve Equation (8) and obtain the state probabilities P_n , we need to evaluate $\sum_{n=0}^{k-1} P_n z^n$. The defined probability generation function $P(z)$ should converge in the interval $|z| \leq 1$, and vanish at all the $(z + 1)$ zeros. Note that, we can use Rouché's theorem to both prove the existence of a certain number of zeros in the domain of regularity for the given function and to satisfy concerns of ergodicity in constructing the solution of the generating function in steady state, as explained in Adan *et al.* [12] and Klimenok [13]. In particular, the denominator of Equation (8) is a $(k + 1)$ degree polynomial, and we need to show that there exist $(k - 1)$ zeros of this polynomial inside $|z| \leq 1$, since $z = 1$ is a zero for both numerator and denominator, leaving exactly one root, say z_0 , outside the unit circle. Note that dividing the denominator of Equation (8) by $(z - z_0)(z - 1)$ will lead to exactly $(k - 1)$ roots in $|z| \leq 1$, and the number of zeros in the numerator of Equation (8) within $|z| \leq 1$ given by $\sum_{n=0}^{k-1} P_n z^n$ must be equal to the roots of denominator, leaving utmost a constant say C ; therefore,

$$\sum_{n=0}^{k-1} P_n z^n = C \frac{1 + \left(\frac{\lambda}{\mu}\right) z^{k+1} - \left(1 + \frac{\lambda}{\mu}\right) z^k}{(z - z_0)(z - 1)}. \quad (9)$$

Substituting the approximation given by Equation (9) into Equation (8) yields the expression

$$P(z) = C \frac{(1 - z^k)}{(z - z_0)(z - 1)} = \frac{C}{(z - z_0)} \sum_{n=0}^{k-1} z^n. \quad (10)$$

Since $P(z)$ is a probability generating function, $P(z = 1) = 1$, which yields $C = \frac{(z_0 - 1)}{K}$ from Equation (10). Substituting this back yields the expression

$$P(z) = \frac{(z_0 - 1) \sum_{n=0}^{k-1} z^n}{K(z_0 - z)}. \quad (11)$$

Expanding the above expression as power series in z gives

$$P_n = \frac{z_0^{n+1} - 1}{K z_0^{n+1}} \quad \text{for } n < k \quad (12)$$

$$P_n = \frac{z_0^k - 1}{K z_0^{n+1}} \quad \text{for } n \geq k. \quad (13)$$

Finding the root z_0 outside the circle $|z| > 1$ is the key to obtaining the system probabilities. Readers are referred to methods and algorithms described in Chaudhry and Templeton [14], Harris *et al.* [15], van Leeuwen and Janssen [16], and Zhao and Campbell [17].

Single-Server Model with General Distribution: $M^{[X]}/G/1$ and $G/M^{[X]}/1$

In the previous sections, we considered bulk queues with Poisson arrival rates and exponential service times. These Markovian assumptions, however, may be relaxed by incorporating general distributions for service containing Poisson batch arrivals, $M^{[X]}/G/1$ queues, and general arrivals having exponential services in batches, $G/M^{[X]}/1$ queues. Due to the non-Markovian nature, both models may be studied using imbedded Markov chains by a straightforward extension of $M/G/1$ and $G/M/1$ queues, [14, Section (2.2.3)]. Additionally, the work of Chaudhry [18] contains an extensive analysis of the $M^{[X]}/G/1$ queue.

EXTENSIONS AND FURTHER READING

An important class of bulk queues includes multiserver (or multichannel) models, in which more than one server is available to process batch arrivals and/or services. The number of available servers can be either finite or infinite; yet, in the latter, only server occupancy will be the measure of interest. Examples of multiserver queues include toll booth, banks, and telephone exchanges. Multiserver bulk models require sophisticated arguments, methods, and involved algebra, yet. Interested readers are referred to Chaudhry and Templeton [14] for a detailed analysis of multiserver models with bulk arrival and service involving finite and infinite servers. In addition, generalizations of Erlangian distributions with a fixed number of phases are extended

to the study of bulk queueing models in Chaudhry and Templeton [14]. They present the analysis of $M/E_k/1$ queue to obtain an implicit solution for bulk input $M^{[X]}/M/1$ queue. The method of phases also helps to analyze non-Markovian models by constructing appropriate phase representation model variables, that is, an $E_k^X/E_r/1$ approximation to a $G^X/G/1$ queue. In general, the technique of matrix geometric methods (MGM) has been heavily used to study bulk queueing models to obtain steady-state performance measures. Most notably, Neuts [19,20,35] provides several batch arrival models along with methods and techniques for their analysis in his seminal work.

Another variant of bulk queues includes the batch arrival of customers with different priority classes, upon which service is given to customers first of a higher priority class both with and without service preemption. As an example, consider a single-server bulk arrival queue with two types of arrivals (say X_1 and X_2), where X_1 has higher priority over X_2 customers, whereupon they are served according to their respective service distribution (G_1, G_2) , that is, an $M^{[X_1, X_2]}/G_1, G_2/1$ model. Such models are often studied using supplementary variables and can be found in Bhat [21,22] and Chaudhry and Templeton [14]. The state probabilities of these queues are obtained using Rouches theorem, and Able's theorem is employed to obtain the joint probability distribution, from whence the waiting time distributions for both types of customers may be found.

A sampling of other notable extensions and literature related to bulk queueing models is as follows. Prabhu [23] studies stochastic ordering properties of three important family of queueing models, namely $M/G^{[s]}/1$, $G^{[s]}/M/1$, and $M/D/s$ for $s \geq 1$, to obtain bounds for the expected queue lengths and number of batches during busy period. Gaver [24] studied the $M^{[X]}/G/1$ using imbedded Markov chain techniques, and an extensive analysis of this model is also discussed in Chaudhry [18]. The imbedded Markov chain technique has been employed to study the $M/G^{[X]}/1$ queue by considering the number of customers in the

system at the n th group departure epoch, and the $G^{[X]}/M/1$ queue by considering the number of customers in the system just before an arrival epoch [21, Section 6.4]. Chiamsiri and Leonard [25] use a diffusion approximation method to study single-server queues with batch arrival and services. Chen and Renshaw [26] study Markovian queues with bulk arrivals, modified to allow mass arrivals and departures when the queue is idle, to derive useful properties in closed form. Dikong and Dshalalow [27] develop analytical solutions of system performance for bulk input model under an N -policy and r -quorum, which incorporates state-dependent services to control the server capacity by limiting the number of switchovers between idle and busy modes of the server. Chang *et al.* [5] discuss the performance analysis of finite-buffer bulk arrival and service queue with a variable server capacity, as well as obtain numerically stable relationships for system probabilities and queue lengths at arrival, departure, and random epochs. Transient solutions for bulk queues have been obtained for a limited number of models due to analytical and modeling complexities. In this area, however, Jaiswal [28] obtains the transient solution of the bulk service problem, and Selim [29] obtains closed form solutions for the transient probability distribution of the number of customers in the system to ultimately predict the optimal service rates. Powell and Humblet [30] additionally analyze bulk service queue with a general control strategy to develop new computational procedures. Finally, Curry and Feldman [31] studied the $M/M/1$ queue under bulk service rules, Alexander [32] develops solutions for $GI/M/1$ systems with unbounded arrival groups, Baba [33] studied the $GI/M/1$ queue with batch arrivals, and Alfa and He [34] develop an algorithmic analysis of discrete-time $GI^X/G^Y/1$ queues.

BATCH MARKOVIAN ARRIVAL PROCESSES (BMAP)

INTRODUCTION

The batch Markovian arrival process (BMAP) is a stochastic point process that generalizes the standard Poisson process (and other point processes) by allowing for “batches” of arrivals, dependent interarrival times, non-exponential interarrival time distributions, and correlated batch sizes. The Markovian arrival process (MAP) is a special case of the BMAP in which the batch size is restricted to unity. For a detailed description of the MAP, see the article titled *Markovian Arrival Processes* in this encyclopedia.

The origins of the BMAP can be traced to the development of the *versatile Markovian point process* (VMPP) by Neuts [1] whose primary objective was to extend the standard Poisson process to account for more complex customer arrival processes in queueing models. The VMPP is characterized by three distinct classes of batch arrivals, each of which are determined by the transition type of an external Markov process with m transient states and one absorbing state, $m + 1$. One type of arrival is from a Markov-modulated Poisson process (MMPP), and this type occurs during the sojourn of the exogenous process in any of the m transient states. Another type occurs when the Markov process in state i transitions to state j , $j \neq i$, which is an ordinary transition between two transient states. The third type of arrival occurs when the process in transient state i

transitions to the absorbing state, $m + 1$, and then restarts in state j . This type of transition is called an (i, j) -renewal transition, and by virtue of restarting the Markov process, admits the possibility of a “self-transition” from a transient state i to itself. From this description, it is clear that the VMPP is founded upon the notion of a phase-type (PH) distribution, or the distribution of the time to absorption of an absorbing Markov process. Neuts [2] played a major role in advancing the use of the PH-distribution in queueing theory, culminating ultimately in the development of the VMPP.

Lucantoni *et al.* [3] sought to extend the original definition of the VMPP while simultaneously easing its notational burden by defining the MAP. The MAP also uses the concept of arrival dependence upon an external Markov process but does not distinguish between classes of arrivals. The MAP was generalized to the BMAP in Ref. 4 by permitting batch arrivals. Originally it was thought that the VMPP was a special case of the BMAP, and it was only later that Lucantoni and others [5,6] asserted the equivalence of the VMPP and BMAP. The term “BMAP” has persisted due to its widespread acceptance in the stochastic modeling community.

The analysis of queueing systems is assisted by the fact that they may often be modeled, either directly or via embedding, as structured Markov chains. Structured Markov chains are typically classified as two main types: the $GI/M/1$ -type and the $M/G/1$ -type. A well-known third type, the quasi-birth-and-death (QBD) process, can be viewed as the juxtaposition of the other two. Structured Markov chains help facilitate the use of *matrix-analytic methods* in the steady-state analysis of queueing systems with MAP and BMAP input. The use of matrix-analytic methods in the analysis of queueing systems is detailed in Neuts’ two classic texts [7,8], which describe the theory and method underlying the derivation of the stationary distributions of the structured Markov chains. The first queueing model

to be considered is the single-server model with infinite capacity. Ramaswami [9] incorporated the BMAP (or VMPP), which he called the N -process in honor of Neuts, as an arrival process to a single-server queue with generally distributed service times. From this work, a generalization of the Polleczech–Khinchin formula to the $N/G/1$ queue was derived. Basic results for the steady-state analysis of the $MAP/G/1$ queue are provided in Ref. 3. The $BMAP/G/1$ is subsequently considered in Ref. 4, while the first known transient analysis of the $BMAP/G/1$ queue is presented in Ref. 5. Various aspects of the $BMAP/G/1$ continue to be studied, as are queueing variants such as the $D - BMAP/G/1$ and the BMAP retrial queue. See the section titled “Further Reading” for references that pertain to these subjects.

In the sections that follow, we formally define the continuous-time BMAP and provide some basic results including the generation function of its counting process and its fundamental rate. We likewise define the discrete-time batch Markovian process (D-BMAP) and describe a variety of arrival processes that are special cases of the BMAP and D-BMAP. Finally, we will provide suggestions for further reading on the subject for the interested reader to gain a deeper understanding of these versatile arrival processes.

THE CONTINUOUS-TIME BMAP

Let $J \equiv \{J(t) : t \geq 0\}$ be an irreducible, continuous-time Markov chain (CTMC) with state space $E = \{1, 2, \dots, m\}$, where m is a finite, positive integer. The infinitesimal generator matrix of this CTMC is denoted by $\mathbf{Q}$. Suppose J has just entered state $i \in E$. The process spends an exponentially distributed amount of time in state i with rate $\lambda_i = -q_{ii}$, where q_{ii} is the i th diagonal element of $\mathbf{Q}$. The transition that follows this sojourn can be one of two types. For the first type, an “arrival” of batch size k ($k \geq 1$) occurs, and the process transitions to state $j \in E$ with probability $p_{ij}(k)$, where j may be equal to i . For the second type, the batch size is 0 and the process transitions to state $j \neq i$ with probability $p_{ij}(0)$. For each $i \in E$, the probabilities $p_{ij}(k)$ satisfy

$$\sum_{k=1}^{\infty} \sum_{j=1}^m p_{ij}(k) + \sum_{j \in E \setminus \{i\}} p_{ij}(0) = 1. \quad (1)$$

Next, for $k \geq 0$, define the matrices $\mathbf{D}_k = [d_{ij}(k)]_{i,j \in E}$, where

$$d_{ij}(0) = \begin{cases} -\lambda_i, & j = i; \\ \lambda_i p_{ij}(0), & j \neq i; \end{cases} \quad (2)$$

and

$$d_{ij}(k) = \lambda_i p_{ij}(k), \quad i, j \in E, \quad k \geq 1. \quad (3)$$

The matrix $\mathbf{D}_0$ contains the transition rates of J for which no arrivals occur, and the matrices $\{\mathbf{D}_k : k \geq 1\}$ contain the transition rates for which a batch size k occurs. Assuming $\mathbf{D}_0$ is a stable matrix (i.e., it is nonsingular), then the interarrival times will be finite almost surely, which is equivalent to stating that the BMAP will not terminate. From condition (1) and Equations (2) and (3), it is not hard to see that

$$\mathbf{Q} = \sum_{k=0}^{\infty} \mathbf{D}_k.$$

Now, let $N(t)$ denote the total number of arrivals up to time t . The joint process, $(N, J) \equiv \{(N(t), J(t)) : t \geq 0\}$, is called a BMAP. Obviously, it is a Markov process with state space $\{(n, j) : n \geq 0, j \in E\}$ and infinitesimal generator matrix

$$\mathbf{Q}^* = \begin{bmatrix} \mathbf{D}_0 & \mathbf{D}_1 & \mathbf{D}_2 & \mathbf{D}_3 & \dots \\ 0 & \mathbf{D}_0 & \mathbf{D}_1 & \mathbf{D}_2 & \dots \\ 0 & 0 & \mathbf{D}_0 & \mathbf{D}_1 & \dots \\ 0 & 0 & 0 & \mathbf{D}_0 & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}.$$

In the context of a BMAP, $\{J(t) : t \geq 0\}$ is normally called the *phase process* and $\{N(t) : t \geq 0\}$ is the *counting process*. The matrices, $\{\mathbf{D}_k : k \geq 0\}$, are said to form a *representation* of the BMAP; that is, the BMAP is completely specified by these matrices.

Let us now consider the joint probability distribution of $(N(t), J(t))$ via its (probability) generating function. Adopting the notation of

Lucantoni [5], denote the transition functions of (N, J) by

$$\begin{aligned} P_{ij}(n, t) &= \mathbb{P}(N(t) = n, \\ J(t) = j \mid N(0) = 0, J(0) = i), \end{aligned}$$

and define the matrix $\mathbf{P}(n, t) = [P_{ij}(n, t)]_{i,j \in E}$. Then, for each $n \geq 0$ and $t \geq 0$, $\mathbf{P}(n, t)$ satisfies the Chapman–Kolmogorov equations

$$\begin{aligned} \frac{d}{dt} \mathbf{P}(n, t) &= \sum_{r=0}^n \mathbf{P}(r, t) \mathbf{D}_{n-r}, \\ \mathbf{P}(0, 0) &= \mathbf{I}, \end{aligned} \quad (4)$$

where $\mathbf{I}$ is the identity matrix of order m . Define the matrix-generating function of $\mathbf{P}(n, t)$ by

$$\mathbf{P}^*(z, t) = \sum_{n=0}^{\infty} \mathbf{P}(n, t) z^n, \quad |z| \leq 1, t \geq 0. \quad (5)$$

Differentiating both sides of Equation (5) with respect to t , substituting Equation (4), and summing shows that

$$\begin{aligned} \frac{d}{dt} \mathbf{P}^*(z, t) &= \mathbf{P}^*(z, t) \mathbf{D}(z), \quad t \geq 0, \\ \mathbf{P}^*(z, 0) &= \mathbf{I}, \end{aligned} \quad (6)$$

where

$$\mathbf{D}(z) \equiv \sum_{k=0}^{\infty} \mathbf{D}_k z^k, \quad |z| \leq 1. \quad (7)$$

The (ordinary) matrix differential equation, Equation (6), has the obvious solution

$$\begin{aligned} \mathbf{P}^*(z, t) &= \mathbf{P}^*(z, 0) \exp(\mathbf{D}(z)t) = \exp(\mathbf{D}(z)t), \\ |z| &\leq 1, t \geq 0, \end{aligned}$$

where $\exp(A)$ is the matrix exponential of a square matrix A defined by

$$\exp(A) = \sum_{i=0}^{\infty} \frac{A^i}{i!}.$$

We pause here to note the similarity between the generating function of the BMAP and

that of a standard Poisson process, which is given by the scalar function

$$P^*(z, t) = \exp((-\lambda + \lambda z)t).$$

For the BMAP, the exponential term $-\lambda + \lambda z$ is replaced by the matrix $\mathbf{D}(z)$ to account for batch sizes larger than unity.

Using the generating function of $\mathbf{P}(n, t)$, one can obtain the (conditional) expectation of the number of arrivals in the interval $(0, t]$. Define this conditional expectation by $\mathbb{E}_i(N(t)\mathbf{1}(J(t) = j))$, where $\mathbf{1}(B)$ denotes the indicator variable of event B and $\mathbb{E}_i$ denotes expectation with respect to $\mathbb{P}_i$, the probability law of (N, J) given $J(0) = i$, and $N(0) = 0$. Then, $\mathbb{E}_i(N(t)\mathbf{1}(J(t) = j))$ is the (i, j) th entry of the $m \times m$ matrix

$$\left. \frac{d}{dz} \mathbf{P}^*(z, t) \right|_{z=1} = \mathbf{D}(1) \exp(\mathbf{D}(1)t) = \mathbf{Q} \exp(\mathbf{Q}t).$$

The conditional k th-factorial moment can be obtained by taking the k th-order derivative $\mathbf{P}^*(z, t)$ and evaluating at $z = 1$ in the usual way.

The limiting behavior of the continuous-time BMAP is discussed next. Let $\boldsymbol{\pi} = [\pi_1, \dots, \pi_m]$ be the invariant probability vector of the CTMC, $\{J(t) : t \geq 0\}$, with generator matrix $\mathbf{Q}$; that is, $\boldsymbol{\pi}$ is the unique positive solution to the system of equations

$$\boldsymbol{\pi} \mathbf{Q} = \mathbf{0} \quad \text{and} \quad \boldsymbol{\pi} \mathbf{e} = 1,$$

where $\mathbf{0}$ is the zero (row) vector and $\mathbf{e}$ is a (column) vector of ones. Then the *fundamental rate*, or the stationary rate of arrivals in a BMAP, is given by

$$\lambda = \boldsymbol{\pi} \left(\sum_{k=1}^{\infty} k \mathbf{D}_k \right) \mathbf{e}. \quad (8)$$

On the other hand, the arrival rate of *batches* is given by

$$\lambda_g = -\boldsymbol{\pi} \mathbf{D}_0 \mathbf{e},$$

which is never zero since $\mathbf{D}_0$ is assumed to be nonsingular. If all the batch sizes are equal to unity, then the process is a Markovian arrival process (MAP), and $\lambda = \lambda_g$.

In the next section, we describe several arrival processes that are special cases of the BMAP. A working knowledge of PH-distributions is assumed for this discussion. For a thorough treatment of continuous- and discrete-time PH-distributions, the reader should consult Refs 1, 6, 7, 10. A cogent summary of PH-distributions is also provided in **Phase-Type (PH) Distributions**.

COMMON CONTINUOUS-TIME BMAPS

1. *Poisson Process*. If the state space E consists of only a single state (i.e., $m = 1$), the time between “transitions” is exponentially distributed with rate λ , and an arrival of batch size 1 occurs at each transition, then the counting process $\{N(t) : t \geq 0\}$, is a Poisson process with rate λ . In this case, the matrices $\{D_k : k \geq 0\}$ are replaced by scalars $\{D_k : k \geq 0\}$. Specifically, $D_0 = -\lambda$, $D_1 = \lambda$, and $D_k = 0$ for all $k \geq 2$. Then, $\{N(t) : t \geq 0\}$ is a BMAP with generator matrix

$$Q^* = \begin{bmatrix} -\lambda & \lambda & 0 & 0 & 0 & 0 & \dots \\ 0 & -\lambda & \lambda & 0 & 0 & 0 & \dots \\ 0 & 0 & -\lambda & \lambda & 0 & 0 & \dots \\ 0 & 0 & 0 & -\lambda & \lambda & 0 & \dots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}.$$

2. *Batch Poisson Process*. If we allow a batch size greater than unity in the standard Poisson process with rate λ , the resulting *batch Poisson process* is a BMAP. Let p_k denote the probability that an arrival is of batch size k , $k \geq 1$, and note that $\sum_{k \geq 1} p_k = 1$. For this process, $m = 1$, $D_0 = -\lambda$, and $D_k = \lambda p_k$ for each $k \geq 1$. Then the batch Poisson Process is a BMAP with generator matrix

$$Q^* = \begin{bmatrix} -\lambda & p_1\lambda & p_2\lambda & p_3\lambda & p_4\lambda & p_5\lambda & \dots \\ 0 & -\lambda & p_1\lambda & p_2\lambda & p_3\lambda & p_4\lambda & \dots \\ 0 & 0 & -\lambda & p_1\lambda & p_2\lambda & p_3\lambda & \dots \\ 0 & 0 & 0 & -\lambda & p_1\lambda & p_2\lambda & \dots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}.$$

Moreover, as noted by Lucantoni [5], if $g(z)$ is the generating function of $\{p_k : k \geq 1\}$, then $D(z) = -\lambda + \lambda g(z)$, $|z| \leq 1$.

3. *Batch MMPP*. Consider a Poisson process whose rate is modulated by an exogenous, irreducible Markov process, $\{J(t) : t \geq 0\}$, with state space $\{1, 2, \dots, m\}$ and generator matrix Q . Whenever $J(t) = i$, arrivals are according to a Poisson process with rate λ_i ($\lambda_i > 0$). Define the vector $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_m)$ and let $\Delta(\lambda) = \text{diag}(\lambda)$. Arrivals occur in batches of size k with probability p_k , $k \geq 1$. If $N(t)$ denotes the number of arrivals up to time t , then $\{(N(t), J(t)) : t \geq 0\}$ is a BMAP with $D_0 = Q - \Delta(\lambda)$, $D_k = p_k \Delta(\lambda)$ for $k \geq 1$. (An excellent summary of the standard MMPP is provided by Fischer and Meier-Hellstern [11].)
4. *Batch PH-Renewal Process*. Suppose that arrivals are according to a renewal process, $\{\tau_n : n \geq 0\}$, where τ_n denotes the n th arrival epoch. The PH-renewal process is a renewal process for which the interrenewal times $S_n \equiv \tau_{n+1} - \tau_n$, $n \geq 0$, form an i.i.d. sequence of PH-distributed random variables with representation (α, T) , where T is of order m . Again, let p_k denote the probability that the batch size is k , $k \geq 1$. The batch PH-renewal process is then a BMAP with $D_0 = T$ and $D_k = p_k T^0 \alpha$, $k \geq 1$ where $T^0 = -T e$.
5. *Superposition of Independent BMAPs*. The superposition of N independent BMAPs is again a BMAP. Let $\{D_k(i) : k \geq 0\}$, $i = 1, 2, \dots, N$, denote a collection of N independent BMAPs such that the phase process of the i th BMAP is of order $m(i)$. Let

$$M = \prod_{i=1}^N m(i),$$

and define for each $k \geq 0$ the $M \times M$ matrix D_k by

$$D_k = D_k(1) \oplus \dots \oplus D_k(N),$$

where the operator $\oplus$ is the *Kronecker matrix sum* [8,11]. Then $\{D_k : k \geq 0\}$ is the representation of the superposition of the N independent BMAPs.

THE DISCRETE-TIME BMAP (D-BMAP)

Consider an irreducible discrete-time Markov chain (DTMC) $J \equiv \{J_r : r \geq 0\}$ on the state space $E = \{1, 2, \dots, m\}$ which allows self-transitions. Suppose that the n th transition of J triggers the arrival of a batch of customers of size Y_n ($Y_n \geq 0$), with $Y_0 = 0$. Define the conditional probabilities

$$q_{ij}(k) = \mathbb{P}(X_{n+1} = j, Y_n = k | X_n = i),$$

$$i, j \in E, n \geq 0,$$

which are the joint probabilities of a transition of the discrete-time chain J from i to j and an arrival of batch size $k \geq 0$. Next, define the (substochastic) matrices $\mathbf{D}_k = [q_{ij}(k)]_{i,j \in E}$ and assume that $\mathbf{I} - \mathbf{D}_0$ is nonsingular to ensure that the arrival of one or more customers occurs with probability one. The transition probability matrix of J , denoted by $\mathbf{P}$, is given by

$$\mathbf{P} = \sum_{k=0}^{\infty} \mathbf{D}_k,$$

whose entries are necessarily finite. The matrices $\{\mathbf{D}_k : k \geq 0\}$ completely specify a D-BMAP.

As for the continuous-time BMAP, it is possible to construct a bivariate Markov chain representation of the D-BMAP. For $r \geq 0$, let N_r be the total number of arrivals up to, and including, the r th transition of J . The process $\{N_r : r \geq 0\}$ is the *counting process* of the D-BMAP, which together with the phase process J , allows us to define the bivariate process

$$\{(N_r, J_r) : r \geq 0\},$$

which is a two-dimensional DTMC with transition probability matrix $\mathbf{P}^*$ given by

$$\mathbf{P}^* = \begin{bmatrix} \mathbf{D}_0 & \mathbf{D}_1 & \mathbf{D}_2 & \mathbf{D}_3 & \dots \\ 0 & \mathbf{D}_0 & \mathbf{D}_1 & \mathbf{D}_2 & \dots \\ 0 & 0 & \mathbf{D}_0 & \mathbf{D}_1 & \dots \\ 0 & 0 & 0 & \mathbf{D}_0 & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}.$$

Next, we elucidate an important property connected to the counting process as documented in Ref. 12. Define the r -step transition matrix $\mathbf{P}(n, r)$ whose (i, j) th entry is defined as

$$[\mathbf{P}(n, r)]_{ij} = \mathbb{P}(N_r = n, J_r = j | J_0 = i),$$

$$r \geq 1, n \geq 0.$$

The matrix generating function of $\mathbf{P}(n, r)$, denoted by $\mathbf{P}^*(z, r)$, is given by

$$\mathbf{P}^*(z, r) = \sum_{n=0}^{\infty} \mathbf{P}(n, r) z^n, \quad |z| \leq 1.$$

It can be shown that, for $r \geq 1$,

$$\mathbf{P}^*(z, r) = [\mathbf{P}^*(z, 1)]^r = [\mathbf{D}(z)]^r, \quad |z| \leq 1, \quad (9)$$

where $\mathbf{D}(z) = \sum_{k=0}^{\infty} \mathbf{D}_k z^k$. If $\mathbf{D}(z)$ is known explicitly, then the k th-factorial moments of the number of arrivals in r ($r \geq 1$) transitions can be obtained by computing the k th-order derivative of $\mathbf{P}^*(z, r)$ and evaluating at $z = 1$.

Next, we consider the fundamental rate of the D-BMAP. Let $\boldsymbol{\pi} = [\pi_1, \dots, \pi_m]$ be the invariant probability vector of the phase process J ; that is, $\boldsymbol{\pi}$ is the unique positive solution to the system of equations

$$\boldsymbol{\pi} \mathbf{P} = \boldsymbol{\pi} \text{ and } \boldsymbol{\pi} \mathbf{e} = 1.$$

Then the *fundamental* or stationary arrival rate of the D-BMAP is given by

$$\lambda = \boldsymbol{\pi} \left(\sum_{k=1}^{\infty} k \mathbf{D}_k \right) \mathbf{e}.$$

Here, the stationary batch arrival rate may be computed as

$$\lambda_g = \boldsymbol{\pi} (\mathbf{I} - \mathbf{D}_0) \mathbf{e},$$

which is always nonzero due to the assumption that $\mathbf{I} - \mathbf{D}_0$ is nonsingular. As before, we have $\lambda = \lambda_g$ if the maximum possible batch size is one, as in a discrete-time MAP.

In the next section, we discuss a few common D-BMAPs and point the reader toward more extensive references on the subject.

COMMON DISCRETE-TIME BMAPS

1. *Batch Geometric Process.* Arrivals here are considered to be a sequence of independent trials for which the “success” probability p_0 ($0 < p_0 < 1$) corresponds to a batch size of zero. This process is a D-BMAP with $m = 1$, $D_0 = p_0$, and $D_k = p_k(1 - p_0)$, where $\{p_k : k \geq 1\}$ are the batch-size probabilities conditioned upon the arrival of a batch of size $k \geq 1$. For the single-arrival process, we note that $p_1 = 1$ and $p_k = 0$ for $k \geq 2$, thus giving $D_0 = p_0$, $D_1 = 1 - p_0$, and $D_k = 0$ for $k \geq 2$.
2. *Batch Markov-Modulated Bernoulli Process.* The Markov-Modulated Bernoulli Process (MMBP) is the discrete-time analog of the MMPP. For both, the single-arrival and batch versions of the MMBP, arrivals are triggered by the transitions of an m -state DTMC with transition probability matrix $\mathbf{P}$. If the process ends up in state $j \in \{1, \dots, m\}$, then the probability of an arrival is given by $\eta_j \in (0, 1]$, while the probability of a null arrival is given by $1 - \eta_j$. For notational convenience, define the vector

$$\boldsymbol{\eta} = (\eta_1, \dots, \eta_m).$$

As with the batch geometric process, the conditional probabilities of batch size are given by the sequence $\{p_k : k \geq 1\}$, with the usual adjustments made for the single-arrival version. The batch MMBP may be expressed as a D-BMAP with elements $\mathbf{D}_0 = \Delta(\mathbf{e} - \boldsymbol{\eta})\mathbf{P}$ and $\mathbf{D}_k = p_k \Delta(\boldsymbol{\eta})\mathbf{P}$ for $k \geq 1$.

3. *Batch PH-Renewal Process.* As before, we consider a renewal process whose renewal epochs are the set of points $\{\tau_n : n \geq 0\}$ with interrenewal times $S_{n+1} \equiv \tau_{n+1} - \tau_n$, $n \geq 0$. Here, the i.i.d. sequence of random variables, $\{S_n : n \geq 1\}$, has a discrete PH distribution with representation $(\boldsymbol{\alpha}, \mathbf{T})$ with $\mathbf{T}$ of order m . The process is then a D-BMAP with $\mathbf{D}_0 = \mathbf{T}$ and $\mathbf{D}_k = p_k \mathbf{T}^0 \boldsymbol{\alpha}$, $k \geq 1$, where $\mathbf{T}^0 = -\mathbf{T}\mathbf{e}$ and $\boldsymbol{\alpha}$ is the vector

of initial probabilities for the discrete PH-distribution.

FURTHER READING

The original formulation of the continuous-time BMAP was the VMPP introduced by Neuts [1] in 1979. The current form of the MAP was developed in Ref. 3 as an arrival process to a single-server queueing system, and the extension to the BMAP is detailed in Ref. 5. The D-BMAP first appeared in the works of Blondia [12,13] and has since pervaded the queueing and computer and communications networking literature, just like its continuous-time predecessor. An excellent summary of the BMAP and D-BMAP, along with examples and selected applications, can be found in Ref. 6.

The analysis of queueing systems with BMAP (or related) input processes has received considerable attention in the stochastic modeling community. Specific examples of single-server queueing models with MAP input can be found in Refs 14–18. Machihara [19] examined single-server queues with batch arrivals and state-dependent service times, while Hofmann [20] considered state-dependent batch arrival rates. Krieger *et al.* [21] studied a Markov-modulated $BMAP/G/1$ queue. Queues with BMAP input and server vacations have received much attention, beginning with Ref. 3. Lucantoni [5] provided a nice summary of a number of important results for the $BMAP/G/1$ system. A sampling of the ensuing literature available on the subject can be found in Refs 22–26. Chydzinsky [27] provided a transient analysis of the $MMPP/G/1/k$ loss system, and in Ref. 28, analyzed the first passage time to buffer overflow in the $BMAP/G/1/k$ queue. The processor-sharing queueing discipline in systems with MAP or BMAP input has been studied extensively in Refs 29–31.

Another fruitful area of research has considered queueing systems with BMAP input and retrials. Retrial queueing systems are extensively used to model systems in which customers retry service after encountering a busy (or failed) server. For example,

they are extremely useful for modeling the retransmission of data packets in computer and communications networks, or the call-back behavior of customers in a customer contact center. Some early examples of the BMAP in retrial queues include Refs 32–35. Chakravarthy and Dudin [36,37] introduced single- and multi-server retrial models with group service and exponential retrials. Breuer *et al.* [38] studied a $BMAP/PH/n$ multiserver retrial system, while Li *et al.* [39] introduced the complication of an unreliable server in the BMAP retrial model.

The BMAP has been applied extensively in a number of areas from inventory management [40] to maintenance models [41]. However, the preponderance of applications lies in computer and communications networking, with the bulk of these assuming D-BMAP input processes. The D-BMAP is often used to model specific characteristics of source signals, such as burstiness, in telecommunications systems. Blondia [13] introduced the D-BMAP model, and in Ref. 12, analyzed the steady-state system size distribution of a $D-BMAP/G/1/N$ queue. Van Houdt and Blondia [42] used a D-BMAP to model packet arrivals in a centralized wireless local area network. In Ref. 43, they examined contention resolution in a network among many users generating signals modeled as a D-BMAP. Zhao *et al.* [44] extended the work of Blondia and Casals [45] on the $D-BMAP/PH/1/N$ queue to the case of prioritized service. Queues with PH-distributed service times have proven useful in modeling video streaming over networks, and the addition of a prioritization scheme enhances the usefulness of these models in networks with heterogeneous data streams.

BAYESIAN AGGREGATION OF EXPERTS' FORECASTS

KENNETH C. LICHTENDAHL, JR.
Darden School of Business,
University of Virginia,
Charlottesville, Virginia

INTRODUCTION

A decision maker when faced with an uncertain future often consults multiple experts to help better forecast the future. For example, a supply chain manager may ask several retail managers, who have greater knowledge of consumer demand, to forecast the future demand for a new product. With these forecasts, the supply chain manager has a modeling choice to make: how does he or she aggregate the retail managers' forecasts into a single forecast? This modeling choice is important because the supply chain manager will use the aggregate forecast in the analysis of his or her inventory decision.

When faced with the question of how to aggregate disparate opinions, decision makers routinely average the forecasts reported by experts. The idea that the average forecast produces a good aggregate forecast goes back at least to Galton. In 1906, Galton [1] went to the West of England Fat Stock and Poultry Exhibition and observed that the median of 787 guesses of an ox's weight was within nine pounds of the ox's actual weight. (See Surowiecki [2] for more details on Galton's trip to the country fair.) Although Galton [3] advocated for the "middlemost" (or median) estimate as the voice of the group, Hooker [4] asked Galton [5], "... is the median a nearer approximation to the truth than the mean?" Pearson [6] concurred, noting that "the trustworthiness of a democratic judgment is ... more than confirmed, if the material be dealt with by the 'average' method, not the 'middlemost' judgment..." After all, in the case of Galton's weight-judging competition, the

average estimate outperformed the median estimate, coming within one pound of the of the ox's actual weight.

In a decision analysis, however, the usefulness of the average of some best guesses is limited. Such an average produces an aggregate point estimate, when the decision maker is in need of a full probability distribution. Without a complete distribution, the decision maker risks committing the "flaw of averages"—a version of Jensen's Inequality [7]. For instance, the supply chain manager, without a complete distribution for demand, may mistake the profit at the average demand forecast for the average profit.

A common approach that addresses the limitation of the aggregate point estimate uses the experts' point estimates themselves to estimate the mean and standard deviation of a normally distributed quantity of interest. In a supply chain problem, Fisher and Raman [8] use this approach to estimate demand uncertainty from several experts' point estimates. Their aggregate forecast for demand is a normal distribution with a mean equal to the average of experts' point estimates and a standard deviation proportional to the sample standard deviation of the experts' point estimates. With this approach, when experts rely heavily on a common information source to form their individual beliefs, the aggregate forecast will typically have a low variance. This will occur even though the common information source may indicate that the future is highly uncertain. In the extreme, all experts look at the same data and report the same point estimate. In this situation, the aggregate forecast in this situation would contain no uncertainty about the future. Hence, there is a theoretical shortcoming in the approach of Fisher and Raman [8]. The decision maker may inadvertently discard valuable information about the degree to which the experts' information sources overlap.

The Bayesian approach, on the other hand, asks a decision maker to explicitly model the experts' forecasts as potentially dependent

data [9,10]. First, the decision maker assesses her prior beliefs for the quantity of interest, and then, conditional on the quantity of interest, she assesses the likelihood of the possible experts' forecasts. If there is an overlap in the information the experts use to form their individual beliefs, then the decision maker incorporates this dependence in the likelihood [10]. We call this likelihood the expert likelihood. It is the conditional distribution of the experts' forecasts given the quantity of interest. Finally, once the decision maker hears the experts' forecasts, the decision maker applies Bayes' theorem to update her prior beliefs for the quantity of interest. The result of this updating process is the aggregate forecast, or posterior distribution. It is the conditional distribution of the quantity of interest, given the experts' forecasts.

Although the Bayesian approach to aggregating individual beliefs is straightforward and theoretically sound, assessing the expert likelihood function can be difficult. The decision maker must assess a separate distribution of the experts' forecasts for each possible state of the quantity of interest. One advantage of the Bayesian approach is that the decision maker can form an aggregate distribution from just about anything the experts might report—from point estimates to quantiles, all the way up to full probability distributions. But, because of the intensive nature of the Bayesian's assessment task, many researchers and practitioners prefer to work with linear opinion pools. The linear opinion pool is intuitively appealing because it involves a simple weighted average of the experts' probability distributions [11]. The linear opinion pool, however, shifts most of the assessment burden onto the experts; each expert must report a full probability distribution. For more information on the Bayesian and opinion pooling approaches to aggregating expert opinion, see Clemen and Winkler [12], Cooke [13], and Genest and Zidek [14].

In the next three sections, we present a series of progressively more complicated examples—a kind of tutorial on Bayesian aggregation. The examples we consider are prototypical. They are meant to illustrate how the theory of Bayesian aggregation

applies in three important forecasting settings: forecasts for discrete events, parametric forecasts for continuous quantities, and nonparametric forecasts for continuous quantities. In the section titled "Aggregation of Probabilities for a Discrete Event," we present several Bayesian aggregation models of experts' probabilities for a discrete event. In the section titled "Aggregation of Parametric Forecasts for a Continuous Quantity," we examine the classic Bayesian aggregation model for experts who report parametric distributions for a continuous quantity. In the section titled "Aggregation of Nonparametric Forecasts for a Continuous Quantity," we provide two Bayesian aggregation models for experts who report nonparametric forecasts—either probability or quantile forecasts—for a continuous quantity. In each setting, we break down the assessment of an expert likelihood into the decision maker's judgments of expert discrimination and dependency. An expert's discrimination, or forecasting skill, arises from the dependency between the event of interest and the expert's forecast; and expert dependency arises from the amount of overlap the decision maker thinks there is in the experts' information sources. Finally, in the section titled "Summary," we summarize these Bayesian approaches with a view toward how these assessments can be made in practice.

AGGREGATION OF PROBABILITIES FOR A DISCRETE EVENT

The simplest Bayesian aggregation model involves a decision maker who updates her prior probability distribution for a discrete event, for example, rain or no rain. She updates her prior beliefs based on what one or more experts report are their beliefs for the same event. In this section, we present four examples that illustrate several important features in this updating process. In the first two examples, we move from one expert reporting on a binary event to two experts reporting on a binary event. In both of these examples, the experts have very coarse information sources from which to draw their opinions. In the second two examples,

we move from two experts reporting on a binary event to multiple experts reporting on a general discrete event. In these second two examples, the experts have more refined sources of information from which to draw their opinions.

Model for a Binary Event and One Expert

Suppose a decision maker is planning an outdoor festival in a new city three days from now. The event of interest x_3 is the weather on the day of the festival: either rain ($x_3 = 1$) or no rain ($x_3 = 0$). The decision maker has her prior beliefs $p_0 = \Pr_0(x_3 = 1)$ about rain on the day of the festival and considers sending an observer to the new city for the next two days. When the observer returns from this trip at the end of two days, he will report his beliefs $p_1 = \Pr_1(x_3 = 1)$ about rain on the day of the festival. How should the decision maker update her beliefs about rain on the day of the festival once she hears the observer's report?

To answer this question, suppose the decision maker and observer both believe rain on each of the next three days x_i is identically and independently distributed (iid) according to a Bernoulli distribution $\text{Br}(\theta)$ with parameter $0 < \theta < 1$. The Bernoulli distribution has probability mass function $\Pr_{\text{Br}}(x_i|\theta) = \theta^{x_i}(1 - \theta)^{1-x_i}$. In addition, both the decision maker and observer are Bayesian and share the belief that the Bernoulli distribution's parameter θ is distributed according to a beta distribution $\text{Be}(\alpha, \beta)$ with hyperparameters $0 < \alpha, \beta < 1$. The beta distribution has probability density function $f_{\text{Be}}(\theta|\alpha, \beta) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)}\theta^{\alpha-1}(1-\theta)^{\beta-1}$ where Γ is the gamma function. We represent the inference model for this Bernoulli process with the following hierarchy:

$$\begin{aligned}\theta &\sim \text{Be}(\alpha, \beta) \\ x_i|\theta &\sim_{\text{iid}} \text{Br}(\theta), \quad i = 1, \dots, n,\end{aligned}$$

where “ $\sim$ ” means *is distributed according to*.

To these two Bayesians, the distribution of $(x_{n+1}|x_n, \dots, x_1)$ becomes the beta-binomial distribution $\text{Bb}(\alpha + r, \beta + n - r, 1)$ where $r = \sum_{i=1}^n x_i$ is a sufficient statistic for $(x_n, \dots, x_1)$.

The beta-binomial distribution has the probability mass function

$$\Pr_{\text{Bb}}(x|a, b, c) = \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)\Gamma(a+b+c)} \binom{c}{x} \times \Gamma(a+x)\Gamma(b+c-x).$$

The distribution of any x_i alone is the beta-binomial distribution $\text{Bb}(\alpha, \beta, 1)$. (For more information on this and other Bayesian inference models, see Bernardo and Smith [15].)

If both the decision maker and observer further agree that $(\alpha, \beta) = (1, 1)$, then the decision maker has $p_0 = \Pr_{\text{Bb}}(x_3 = 1|1, 1, 1) = \frac{1}{2}$, and the observer will report $p_1 = \Pr(x_3 = 1|x_2, x_1) = \Pr_{\text{Bb}}(x_3 = 1|1+r, 3-r, 1)$. In Table 1, we see the three possible ways that the observer might report, depending on the outcomes for rain on the first two days.

To update the decision maker's prior beliefs based on the observer's report, the decision maker uses Bayes' theorem to find the conditional distribution of $(x_3|p_1)$ as follows:

$$\Pr(x_3|p_1) = \frac{\Pr(x_3)\Pr(p_1|x_3)}{\Pr(p_1)}.$$

She deduces the distribution of $(p_1|x_3)$ from her beliefs about $(x_1, x_2|x_3)$. This deduction requires a thought experiment—if the decision maker alone knew the outcome on day three what would her beliefs about rain on the first two days be? The distribution of $(x_1, x_2|x_3)$ is given by

$$\begin{aligned}\Pr(x_1, x_2|x_3) &= \frac{\Pr(x_1, x_2, x_3)}{\Pr(x_3)} \\ &= \frac{2\Gamma(1+x_1+x_2+x_3)\Gamma(4-x_1-x_2-x_3)}{\Gamma(5)},\end{aligned}$$

Table 1. Rain Observations and One Observer's Reports

Day 1 Outcome (x_1)	Day 2 Outcome (x_2)	Sufficient Statistic ($r = \sum_{i=1}^2 x_i$)	Observer's Report (p_1)
0	0	0	0.25
0	1	1	0.50
1	0	1	0.50
1	1	2	0.75

Table 2. Rain Observations, Distribution of $(x_1, x_2 | x_3)$, and One Observer's Reports

Day 1 Outcome (x_1)	Day 2 Outcome (x_2)	Day 3 Outcome (x_3)	$\Pr(x_1, x_2 x_3)$	Observer's Report (p_1)
0	0	0	1/6	0.25
0	1	0	1/6	0.50
1	0	0	1/6	0.50
1	1	0	3/6	0.75
0	0	1	3/6	0.25
0	1	1	1/6	0.50
1	0	1	1/6	0.50
1	1	1	1/6	0.75

where the second equality follows from substitution according to $\Pr(x_3) = \frac{1}{2}$ and

$$\Pr(x_1, x_2, x_3) = \int_0^1 f_{\text{Be}}(\theta | 1, 1) \theta^{x_1} (1 - \theta)^{1-x_1} \theta^{x_2} \times (1 - \theta)^{1-x_2} \theta^{x_3} (1 - \theta)^{1-x_3} d\theta.$$

The distribution of $(x_1, x_2 | x_3)$, which is listed in Table 2, leads to the two conditional distributions in Fig. 1 that make up the expert likelihood $\Pr(p_1 | x_3)$.

The conditional distributions depicted in Fig. 1 look as we would expect them to look. If it is going to rain on the third day, then the decision maker believes it is more likely the expert will report a high p_1 . If it is not going to rain on the third day, then the decision maker believes it is more likely the expert will report a low p_1 . This feature of the expert likelihood is called *discrimination*

[16]. The less similar the expert likelihood's two conditional distributions are, the more discriminating or skilled, we say the expert is. Another way to say this is: the more correlated (either negatively or positively) the quantity of interest and the expert's report are, the more discriminating the expert is.

Finally, using the fact that the distribution of p_1 is $\Pr(p_1) = \Pr(x_3 = 1) \Pr(p_1 | x_3 = 1) + \Pr(x_3 = 0) \Pr(p_1 | x_3 = 0)$, the decision maker updates her beliefs to find, not surprisingly, that the aggregate distribution is $\Pr(x_3 | p_1) = p_1$. It is as if the decision maker observed the first two days of the weather herself.

Model for a Binary Event and Two Overlapping Experts

To incorporate the idea that the information experts access may overlap, we consider the

**Figure 1.** Expert likelihood for one observer.

situation in the section titled “Model for a Binary Event and One Expert” with a second observer who visits the new city on the second and third days. The decision maker is now planning the outdoor event in the new city on the fourth day. When the two observers return from their trips—the first observer at the end of two days and the second observer at the end of three days—they will report their beliefs p_1 and p_2 about rain on the fourth day. How should the decision maker update her beliefs about rain on the fourth day once she hears the observers’ report?

To answer this question, we suppose the decision maker and the observers agree on the inference model for the Bernoulli process in the section titled “Model for a Binary Event and One Expert” with the same hyperparameters $(\alpha, \beta) = (1, 1)$. Then, the decision maker has $p_0 = \Pr(x_4 = 1) = \Pr_{\text{Bb}}(x_4 = 1 | 1, 1, 1) = \frac{1}{2}$. Observer 1 will report $p_1 = \Pr(x_4 = 1 | x_2, x_1) = \Pr_{\text{Bb}}(x_4 = 1 | 1 + r_1, 3 - r_1, 1)$ where $r_1 = \sum_{i=1}^2 x_i$. Observer 2 will report $p_2 = \Pr(x_4 = 1 | x_3, x_2) = \Pr_{\text{Bb}}(x_4 = 1 | 1 + r_2, 3 - r_2, 1)$ where $r_2 = \sum_{i=2}^3 x_i$. In Table 3, we see the eight possible ways the observers might report, depending on the outcomes for rain on the first three days.

To update the decision maker’s prior beliefs based on the observers’ reports, the decision maker uses Bayes’ theorem to find the conditional distribution of $(x_4 | p_1, p_2)$ as follows:

$$\Pr(x_4 | p_1, p_2) = \frac{\Pr(x_4) \Pr(p_1, p_2 | x_4)}{\Pr(p_1, p_2)}.$$

She deduces the distribution of $(p_1, p_2 | x_4)$ from her distribution of $(x_1, x_2, x_3 | x_4)$:

$$\begin{aligned} \Pr(x_1, x_2, x_3 | x_4) &= \frac{\Pr(x_1, x_2, x_3, x_4)}{\Pr(x_4)} \\ &= \frac{2\Gamma\left(1 + \sum_{i=1}^4 x_i\right) \Gamma\left(5 - \sum_{i=1}^4 x_i\right)}{\Gamma(6)}. \end{aligned}$$

In Fig. 2, we see the conditional distributions that make up the expert likelihood $\Pr(p_1, p_2 | x_4)$. When p_1 (or p_2) is “integrated” out of this joint likelihood $\Pr(p_1, p_2 | x_4)$, the distributions of $p_1 | x_4$ (or $(p_2 | x_4)$) is the same as those depicted in Fig. 1. Thus, the second expert is as discriminating as the first expert. However, the experts’ reports are not independent; in either case ($x_4 = 1$ or $x_4 = 0$), the experts’ reports have a correlation, $\text{Corr}[p_1, p_2 | x_4]$, of 0.7. This dependency between the experts’ reports is due to two facts: (i) the data themselves are dependent, and (ii) both experts observe the weather on the second day. If expert 2 were not to observe the weather on day 2, the experts’ reports would have the lower correlation of 0.267. Note that without informational overlap, the experts’ reports are still dependent because beliefs about x_3 are affected by knowledge of (x_1, x_2) via the inferential model for the Bernoulli process above. Without this dependency, the experts’ report would have no relevance to the quantity of interest, and consulting the experts would be pointless.

Finally, once the decision maker updates her beliefs, she finds the aggregate forecast is one of the probabilities listed in Table 4.

Table 3. Rain Observations and Two Observer’s Reports

Day 1 Outcome (x_1)	Day 2 Outcome (x_2)	Day 3 Outcome (x_3)	Sufficient Statistic ($r_1 = \sum_{i=1}^2 x_i$)	Observer 1’s Report (p_1)	Sufficient Statistic ($r_2 = \sum_{i=2}^3 x_i$)	Observer 2’s Report (p_2)
0	0	0	0	0.25	0	0.25
0	0	1	0	0.25	1	0.50
0	1	0	1	0.50	1	0.50
0	1	1	1	0.50	2	0.75
1	0	0	1	0.50	0	0.25
1	0	1	1	0.50	1	0.50
1	1	0	2	0.75	1	0.50
1	1	1	2	0.75	2	0.75

Figure 2. Expert likelihood for two observers.

Table 4. Aggregate Probabilities for Two Observers where $i = 1, 2$ and $i \neq j$

Observer i 's Report (p_i)	Observer j 's Report (p_j)	Aggregate Probability $\Pr(x_4 p_i, p_j)$
0.25	0.25	0.20
0.25	0.50	0.40
0.50	0.50	0.50
0.50	0.75	0.60
0.75	0.75	0.80

At the extremes, when the experts both report either 0.25 or 0.75, the aggregate forecast is even more extreme—either below 0.25 or above 0.75, respectively. These extreme aggregate forecasts make sense because in these cases, the experts observe either no days of rain or all days of rain. In between these extremes, the decision maker finds some compromise, and even unanimity, among the two experts. For more detail on the issues of unanimity and compromise among forecasters, see Clemen and Winkler [17].

Model for a Binary Event and Two Experts with More Refined Information Sources

Suppose the decision maker believes her experts' information is more refined than observing rain on two days. In the previous

section, each of the experts' reports p_1 and p_2 could take one of only three possible values. These experts relied on a coarse information source—rain or not on two previous days. With more refined information on the previous days' temperature, pressure, and humidity, the decision maker might believe each of the experts' reports p_1 and p_2 can take any value between 0 and 1. In this situation, as in most real-world situations, the decision maker will want an expert likelihood that is a continuous distribution.

One of the leading models of a continuous expert likelihood uses the experts' log odds ratios, $l_1 = \log \frac{p_1}{1-p_1}$ and $l_2 = \log \frac{p_2}{1-p_2}$, instead of their probabilities, (p_1, p_2) . The reason a decision maker may want to work with the experts' log odds ratios is so that she can use the multivariate normal distribution as an expert likelihood. Whereas probabilities take values on the interval $[0, 1]$, log odds ratios take values on the same interval that normally distributed quantities take, namely $(-\infty, \infty)$. The main advantage of the multivariate normal distribution is its tractable dependency structure. With the multivariate normal distribution, the decision can assess the dependency between her experts' reported log odds with a single parameter ρ_x as follows:

$$(l_1, l_2)' | x \sim N(\mu_x, \Sigma_x), \quad (1)$$

where $\mu_x = \begin{pmatrix} \mu_{x,1} \\ \mu_{x,2} \end{pmatrix}$ is its mean vector and $\Sigma_x = \begin{pmatrix} \sigma_{x,1}^2 & \rho_x \sigma_{x,1} \sigma_{x,2} \\ \rho_x \sigma_{x,1} \sigma_{x,2} & \sigma_{x,2}^2 \end{pmatrix}$ is its correlation matrix. The higher the decision maker sets $\mu_{1,i}$ relative to $\mu_{0,i}$, the more discriminating she believes her experts are. With the correlation coefficient $\rho_x = \text{Corr}[l_1, l_2|x]$, the decision maker incorporates her view of the dependency between the experts' reports. The more she thinks the experts' information sources overlap, the higher she might set this correlation coefficient.

After hearing the experts' forecasts for rain and computing their reported log odds ratios, the decision maker updates her prior beliefs $p_0 = \Pr(x = 1)$ to find the aggregate forecast:

$$\Pr(x = 1|l_1, l_2) = \frac{\Pr(x = 1)f(l_1, l_2|x = 1)}{f(l_1, l_2)} \\ = \frac{p_0 f_N(l_1, l_2|\mu_1, \Sigma_1)}{p_0 f_N(l_1, l_2|\mu_1, \Sigma_1) + (1-p_0)f_N(l_1, l_2|\mu_0, \Sigma_0)}.$$

This model can be scaled up to handle more than two experts [12]. In addition, a decision maker can use the logistic-normal distribution, which is a distribution for more than one log odds ratio [18], to handle discrete events with more than two outcomes. In the following section, we discuss an alternative model for aggregating experts' forecasts of a discrete event with more than two outcomes.

Model for a General Discrete Event and Multiple Experts

Since Lindley and Smith [19], Bayesian hierarchical modeling has become an attractive way to model the dependency between data [15,20]. In the aggregation problem, because the experts' probability forecasts are data, a decision maker may use a Bayesian hierarchical model to aggregate experts' probabilities for a general discrete event. At the bottom level of the hierarchy, the decision maker might use the popular Dirichlet for each expert's probabilities.

Suppose a decision maker uses the following hierarchical model for aggregating beliefs about a discrete event x , taking values $0, 1, \dots$, or m :

$$x \sim p_0 \\ \alpha(j)|x \sim \text{iid } \text{Ga}(a_x(j), b_x(j)), \quad j = 0, 1, \dots, m \\ p_i|\alpha, x \sim \text{iid } \text{Dir}(\alpha), \quad i = 1, \dots, k$$

where (i) the decision maker's and k experts' prior beliefs are given by $p_i = (\Pr_i(x = 0), \dots, \Pr_i(x = m))$ for $i = 1, \dots, k$, (ii) $\alpha_x = (a_x(0), \dots, a_x(m))$ and $b_x = (b_x(0), \dots, b_x(m))$ are the hyperparameters in the gamma distributions $\text{Ga}(a_x(j), b_x(j))$ with probability density function $f_{\text{Ga}}(\alpha(j)|a_x(j), b_x(j)) = \frac{b_x(j)^{a_x(j)}}{\Gamma(a_x(j))} \alpha(j)^{a_x(j)-1} e^{-b_x(j)\alpha(j)}$ for $j = 0, 1, \dots, m$, and (iii) $\alpha = (\alpha(0), \dots, \alpha(m))$ is the common parameter in the expert likelihood, a Dirichlet distribution with probability density function

$$f_{\text{Dir}}(p_0, \dots, p_{m-1}|\alpha) \\ = \frac{\Gamma\left(\sum_{j=0}^m \alpha(j)\right)}{\Gamma(\alpha(0))\Gamma(\alpha(1))\dots\Gamma(\alpha(m))} p_0^{\alpha(0)-1} p_1^{\alpha(1)-1} \dots \\ p_{m-1}^{\alpha(m-1)-1} \left(1 - \sum_{j=0}^m p_j\right)^{\alpha(m)-1}$$

In this model, the larger the decision maker sets the means $\frac{a_x(j)}{b_x(j)}$ for $j = x$, the more dependent the quantity of interest and the experts' reports are, and thus, the more discriminating she thinks the experts are. In addition, the larger she sets the variances $\frac{a_x(j)}{b_x(j)^2}$ for $j = 0, 1, \dots, m$, the more dependent she thinks the experts' reports are. Although the decision maker assumes the experts' forecasts are exchangeable in the model above, she can extend the model to allow for expert-specific α_i , $a_{x,i}$, and $b_{x,i}$ for $i = 1, \dots, k$. Such a model might include another level in the hierarchy so that the experts' hyperparameters $a_{x,i}$, and $b_{x,i}$ for $i = 1, \dots, k$ are exchangeable.

One of the earliest Bayesian aggregation models is a version of the Dirichlet model above. Morris [9] proposes a beta model where $m = 1$ and $\Pr_0(x = 0) = \frac{1}{2}$. (When $m = 1$, the Dirichlet distribution and the beta distribution are one and the same.) Instead of the gamma distribution above, he uses

a fixed parameter $\alpha = (2(1-x) + 1, 2x + 1)$. Because he assumes no variance in α , Morris' experts are independent and the conditional distributions of the expert likelihood are beta distributions and are similar in shape, although continuous, to those in Fig. 1 from the section titled "Model for a Binary Event and One Expert." If a decision maker thought her experts' reports were conditionally independent and their sources of information quite refined, then she might employ Morris' beta model.

AGGREGATION OF PARAMETRIC FORECASTS FOR A CONTINUOUS QUANTITY

When an uncertain quantity of interest can take any value in a continuous range of possible values, a decision maker may ask her experts to report their means for this continuous quantity. The leading Bayesian model for this sort of aggregation is Winkler's [10] normal consensus model:

$$x \sim \mathbf{v} \\ (\mu_1, \dots, \mu_k)' | x \sim N((x, \dots, x)', \Sigma),$$

where $\mathbf{v}$ is the noninformative (or vague) prior distribution with a constant probability density function $f_{\mathbf{v}}(x) = c$ on the entire real line, and the experts' means $\boldsymbol{\mu} = (\mu_1, \dots, \mu_k)'$ are jointly normally distributed with mean vector $(x, \dots, x)'$ and covariance matrix Σ , regardless of the value of x . In this model, the decision maker lacks a proper point of view: the integral of her prior density over the entire real line does not exist. Here, the multivariate normal distribution constitutes the expert likelihood. After Bayesian updating, the aggregate forecast for x is again normal:

$$x | \mu_1, \dots, \mu_k \sim N\left(\frac{\mathbf{e}' \Sigma^{-1} \boldsymbol{\mu}}{\mathbf{e}' \Sigma^{-1} \mathbf{e}}, (\mathbf{e}' \Sigma^{-1} \mathbf{e})^{-1}\right)$$

where $\mathbf{e}' = (1, \dots, 1)$ is a $(1 \times k)$ vector.

Lindley [21,22] extends Winkler's model to handle experts' measures of location, spread, and skewness. In many cases, reported location and spread measures, for example, mean and variance, will fully specify an

expert's probability distribution. In these cases, an expert's location and spread measures completely parameterize the expert's forecast (e.g., normal, gamma, beta, etc.), and we say the expert reports a parametric forecast for a continuous quantity.

Importantly, the expert likelihood above may arise from experts who access overlapping information that is exchangeable with the quantity of interest [10,23,24]. In the following example, we consider a related situation where the decision maker has a proper point of view, that is, her prior distribution of the quantity of interest is a proper distribution [25]. Suppose the decision maker and two experts share the belief that the data $(x_1, \dots, x_{n+1})$ follows a normal process with an unknown, normal mean θ and a known variance σ^2 :

$$\theta \sim N(\mu_0, \sigma_0^2) \\ x_i | \theta \sim_{\text{iid}} N(\theta, \sigma^2), \quad i = 1, \dots, n+1$$

These data might be temperatures on four consecutive days in a new city. The decision maker plans to aggregate the experts' forecasts for the temperature on the fourth day, once the experts return from their overlapping trips to the new city. Expert 1 observes the temperature on day 1, expert 2 observes the temperature on day 3, and both experts observe the temperature on day 2.

After observing their respective samples, expert 1 holds the following posterior-predictive beliefs [15, p. 439]:

$$x_4 | x_2, x_1 \sim N\left(\frac{\lambda_0 \mu_0 + \lambda(x_1 + x_2)}{\lambda_0 + 2\lambda}, \frac{\lambda_0 + 3\lambda}{\lambda(\lambda_0 + 2\lambda)}\right),$$

where $\lambda_0 = \frac{1}{\sigma_0^2}$ and $\lambda = \frac{1}{\sigma^2}$ are the precisions of the process, and similarly, expert 2 holds the following posterior-predictive beliefs:

$$x_4 | x_3, x_2 \sim N\left(\frac{\lambda_0 \mu_0 + \lambda(x_2 + x_3)}{\lambda_0 + 2\lambda}, \frac{\lambda_0 + 3\lambda}{\lambda(\lambda_0 + 2\lambda)}\right).$$

Thus, each expert can report the mean μ_i of his posterior-predictive distribution without any loss of information. This situation of informational overlap parallels the one in the

section titled “Model for a Binary Event and Two Overlapping Experts” where two experts observed data from a Bernoulli process.

To update the decision maker's prior beliefs based on the experts' reports, the decision maker uses Bayes' theorem to find the conditional distribution of x_{n+1} given the experts' reports (μ_1, μ_2) :

$$f(x_4|\mu_1, \mu_2) = \frac{f(x_4)f(\mu_1, \mu_2|x_4)}{f(\mu_1, \mu_2)}$$

In this case, the decision maker deduces both the distribution of $(\mu_1, \mu_2|x_4)$ and the distribution of $(x_4|\mu_1, \mu_2)$ directly from her joint predictive distribution:

$$(x_1, x_2, x_3, x_4)' \sim N \left((\mu_0, \mu_0, \mu_0, \mu_0)', \begin{pmatrix} \sigma^2 + \sigma_0^2 & \sigma_0^2 & \sigma_0^2 & \sigma_0^2 \\ \sigma_0^2 & \sigma^2 + \sigma_0^2 & \sigma_0^2 & \sigma_0^2 \\ \sigma_0^2 & \sigma_0^2 & \sigma^2 + \sigma_0^2 & \sigma_0^2 \\ \sigma_0^2 & \sigma_0^2 & \sigma_0^2 & \sigma^2 + \sigma_0^2 \end{pmatrix} \right).$$

Because the data are exchangeable in this model, the correlation coefficients $\rho_{ij} = \text{Corr}[x_i, x_j]$ in this joint predictive distribution are all the same $\rho_{ij} = \frac{\sigma_0^2}{\sigma^2 + \sigma_0^2}$. With a change of variables from $(x_1, x_2, x_3, x_4)'$ to $(x_4, \mu_1, \mu_2, x_2)'$, according to the linear transformation $(x_4, \mu_1, \mu_2, x_2)' = \mathbf{a} + \mathbf{B}(x_1, x_2, x_3, x_4)'$

where $\mathbf{a} = \left(0, \frac{\lambda_0 \mu_0}{\lambda_0 + 2\lambda}, \frac{\lambda_0 \mu_0}{\lambda_0 + 2\lambda}, 0\right)'$ and

$$\mathbf{B} = \begin{pmatrix} 0 & 0 & 0 & 1 \\ \frac{\lambda}{\lambda_0 + 2\lambda} & \frac{\lambda}{\lambda_0 + 2\lambda} & 0 & 0 \\ 0 & \frac{\lambda}{\lambda_0 + 2\lambda} & \frac{\lambda}{\lambda_0 + 2\lambda} & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

we have

$$(x_4, \mu_1, \mu_2, x_2)' \sim N \left((\mu_0, \mu_0, \mu_0, \mu_0)', \begin{pmatrix} \frac{\lambda_0 + \lambda}{\lambda_0 \lambda} & \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)} & \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)} & \frac{1}{\lambda_0} \\ \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)} & \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)} & \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)^2} & \frac{1}{\lambda_0} \\ \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)} & \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)} & \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)^2} & \frac{1}{\lambda_0} \\ \frac{1}{\lambda_0} & \frac{1}{\lambda_0} & \frac{1}{\lambda_0} & \frac{\lambda_0 + \lambda}{\lambda_0 \lambda} \end{pmatrix} \right)$$

This distribution follows from the standard formula for a linear transformation of a jointly normal vector [26, p. 637].

Because $(x_4, \mu_1, \mu_2, x_2)'$ is jointly normally distributed, we can find both the expert likelihood and the aggregate distribution

by applying the standard formulas to find the marginal and conditional distributions of partitions of a jointly normal vector [26, p. 637]. First, the marginal distribution of the partition $(x_4, \mu_1, \mu_2)'$ is given by

$$(x_4, \mu_1, \mu_2)' \sim N \left((\mu_0, \mu_0, \mu_0)', \begin{pmatrix} \frac{\lambda_0 + \lambda}{\lambda_0 \lambda} & \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)} & \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)} \\ \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)} & \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)} & \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)^2} \\ \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)} & \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)} & \frac{2\lambda}{\lambda_0(\lambda_0 + 2\lambda)^2} \end{pmatrix} \right)$$

The quantity of interest and either expert's mean are positively correlated with correlation coefficient $\frac{\sqrt{2\lambda}}{\sqrt{(\lambda_0 + 2\lambda)(\lambda_0 + \lambda)}}$, which increases as uncertainty σ_0^2 about the unknown mean of the data increases.

The higher this correlation, the more discriminating the expert is.

Next, the expert likelihood is given by the conditional distribution of the partition $(\mu_1, \mu_2)'$ given the partition x_4 of the jointly normal vector $(x_4, \mu_1, \mu_2)'$:

$$(\mu_1, \mu_2)' | x_4 \sim N \left(\begin{pmatrix} \frac{\lambda_0(\lambda_0+3\lambda)\mu_0+2\lambda^2x_4}{(\lambda_0+2\lambda)(\lambda_0+\lambda)} \\ \frac{\lambda_0(\lambda_0+3\lambda)\mu_0+2\lambda^2x_4}{(\lambda_0+2\lambda)(\lambda_0+\lambda)} \end{pmatrix}, \begin{pmatrix} \frac{2\lambda(\lambda_0+3\lambda)}{(\lambda_0+2\lambda)^2(\lambda_0+\lambda)} & \frac{\lambda(\lambda_0+5\lambda)}{(\lambda_0+2\lambda)^2(\lambda_0+\lambda)} \\ \frac{\lambda(\lambda_0+5\lambda)}{(\lambda_0+2\lambda)^2(\lambda_0+\lambda)} & \frac{2\lambda(\lambda_0+3\lambda)}{(\lambda_0+2\lambda)^2(\lambda_0+\lambda)} \end{pmatrix} \right)$$

In part, because the experts' information sources overlap, the correlation coefficient of the experts' means, given the quantity of interest, is $\frac{\lambda_0+5\lambda}{2\lambda_0+6\lambda}$.

Finally, the aggregate distribution is given by the conditional distribution of the partition x_4 given the partition $(\mu_1, \mu_2)'$:

$$x_4 | \mu_1, \mu_2 \sim N \left(\frac{2(\lambda_0+2\lambda)(\mu_1+\mu_2)-\lambda_0\mu_0}{(3\lambda_0+8\lambda)}, \frac{3\lambda_0+11\lambda}{\lambda(3\lambda_0+8\lambda)} \right).$$

Had the decision maker consulted with only expert 1, her aggregate distribution would not surprisingly, be given by $x_4 | \mu_1 \sim N \left(\mu_1, \frac{\lambda_0+3\lambda}{\lambda(\lambda_0+2\lambda)} \right)$, which is identical to expert 1's report. Similar to the observations in the sections titled "Model for a Binary Event and One Expert" and "Model for a Binary Event and Two Overlapping Experts," it is as if she observed the temperature on the first two days herself.

A decision maker who wishes to aggregate experts' reported means (or location parameters from a parametric distribution) may use the above example in a thought experiment. She might assess expert discrimination by thinking about each expert's experience in terms of the quantity and quality of the relevant data that the expert has observed. In addition, she might assess expert dependency by thinking about her experts in terms of how much overlap there is in the experts' experiences.

AGGREGATION OF NONPARAMETRIC FORECASTS FOR A CONTINUOUS QUANTITY

Often times a decision maker will find the assumption that an expert reports according to a parametric distribution too restrictive. In these situations, the decision maker may believe an expert's forecast comes from a highly customized, or nonparametric, distribution. In practice, a decision maker typically elicits such a nonparametric forecast by one

of two methods: either (i) by asking for several quantiles from the expert's quantile function, or (ii) by asking for several probabilities from the expert's cumulative distribution function. In this section, we present two models (one for each method) a decision maker may use to assess an expert likelihood for nonparametric forecasts.

Model for Nonparametric Quantile Forecasts

The earliest model for updating upon hearing an expert's nonparametric quantile forecasts is the following model [27]:

$$x \sim F_0 \\ G_x(Q_1) | x \sim \text{DP}(c\lambda)$$

where (i) F_0 is the decision maker's prior distribution with density $f_0(x)$, (ii) Q_1 is the expert's reported quantile function, $Q_1(u) = \min\{u : F_1(x) \geq u\}$, which is derived from the expert's cumulative distribution function F_1 , (iii) G_x is a distribution function, indexed by x , and (iv) $\text{DP}(c\lambda)$ is a Dirichlet process with a parameter $c\lambda$ that measures the interval $(u_i, u_j]$ as follows:

$$c\lambda((u_i, u_j]) = c(u_j - u_i)$$

where c is a scalar.

The Dirichlet process is the leading model used in Bayesian nonparametric statistics to describe uncertainty about a random distribution function [28,29]. The Dirichlet process is a stochastic process F defined by its finite-dimensional Dirichlet distributions. In particular, the increments of the random distribution function F evaluated at a set of points in any partition of x 's state space $x_0 < x_1 < x_2 < \dots < x_m < x_{m+1}$ are distributed according to a Dirichlet distribution:

$$(F(x_1) - F(x_0), F(x_2) - F(x_1), \dots, F(x_{m+1}) - F(x_m)) \sim \text{Dir}(\alpha((x_0, x_1]), \dots, \alpha((x_m, x_{m+1}]),$$

where α called the process's centering measure because $E[F(x_{j+1}) - F(x_j)] = \alpha(x_j, x_{j+1})$.

In West's [27] model, the Dirichlet process is used in a related way to describe uncertainty about a function G_x of a random quantile function Q_1 .

In West's [27] model above, the distribution function G_x is called a *target distribution* and is the main ingredient in the expert likelihood. For example, suppose $G_{x,\theta}$ is a beta target distribution with density

$$g_{x,\theta}(q) = f_{\text{Be}}(F_0(q)|\theta F_0(x) + 1, \theta(1 - F_0(x)) + 1)f_0(q),$$

where $\theta > -1$ is a discrimination parameter that further indexes the target [30, pp. 76–81]. When $\theta = 0$, $g_{x,\theta}(q) = f_0(q)$: the decision maker believes the expert is noninformative. As $\theta \rightarrow \infty$, $G_{x,\theta}$ goes to a point mass of 1 at x : the decision maker believes the expert is a clairvoyant. For $\theta \in (0, \infty)$, the decision maker expects the expert to report more of his probability around x than she assessed with her prior.

For the expert who reports his m quantiles $Q_1(u_1), \dots, Q_1(u_m)$ where $0 = u_0 < u_1 < \dots < u_m < u_{m+1} = 1$, West's [27] expert likelihood becomes

$$G_{x,\theta}(Q_1(u_1)) - G_{x,\theta}(Q_1(u_0)), \dots, G_{x,\theta}(Q_1(u_{m+1})) - G_{x,\theta}(Q_1(u_m)) \sim \text{Dir}(c\lambda),$$

where $c\lambda = (c\lambda((u_0, u_1]), \dots, c\lambda((u_m, u_{m+1}]))$. After Bayesian updating, the density $f(x|Q_1(u_1), \dots, Q_1(u_m))$ is proportional to

$$f(x) f_{\text{Dir}}(G_{x,\theta}(Q_1(u_1)) - G_{x,\theta}(Q_1(u_0)), \dots, G_{x,\theta}(Q_1(u_{m+1})) - G_{x,\theta}(Q_1(u_m)) | c\lambda) \times \prod_{j=1}^m g_{x,\theta}(Q_1(u_j)).$$

West's [27] model easily extends to incorporate more than just one expert's quantile forecasts. For example, the following hierarchical model, which is similar to the one discussed in the section titled "Model for a General Discrete Event and Multiple Experts," can be used to aggregate multiple experts' nonparametric quantile forecasts:

$$\begin{aligned} x &\sim F_0 \\ (\theta + 1)|x &\sim \text{Ga}(a, b) \\ G_{x,\theta}(Q_i)|c, x &\sim \text{iid DP}(c\lambda), \quad i = 1, \dots, k. \end{aligned}$$

Although West's [27] model involves a straightforward application of the Dirichlet process, we offer a technical note of caution about the Dirichlet process in this context. The Dirichlet process puts all of its probability on a set of discrete distribution functions. That is, it inherits the properties of a stochastic process with an infinite number of jumps occurring at random places in x 's state space with random heights [28]. In the limit, as the decision maker elicits an expert's entire continuous quantile function, the Dirichlet process breaks down. Contrary to the claim in West [27, Theorem 2], the decision maker cannot use the Dirichlet process as a proper likelihood for an expert's entire continuous quantile function [30, pp. 35–37]. In other words, she cannot update on an event that was assigned probability zero.

Nonetheless, the Dirichlet process is a good approximation for the distribution of a random continuous distribution function or, as West [27] uses it, the distribution of a function of a random continuous quantile function. West's [27] model works perfectly fine for any finite number of reported quantiles. This is because it assigns a reasonable continuous distribution (as an expert likelihood) to any finite number of reported quantiles.

Model for Nonparametric Probability Forecasts

We offer the following model for a decision maker who elicits a finite number of expert's probabilities $\mathbf{p}_i = (F_i(x_1), F_i(x_2) - F_i(x_1), \dots, 1 - F_i(x_m))$ over any partition of x 's state space $x_0 < x_1 < x_2 < \dots < x_m < x_{m+1}$, which is analogous to the one in the section titled "Model for a General Discrete Event and Multiple Experts":

$$\begin{aligned} x &\sim F_0 \\ \alpha|x &\sim \text{GP}(a_x, b_x) \\ \mathbf{p}_i|\alpha, x &\sim \text{iid DP}(\alpha), \quad i = 1, \dots, k. \end{aligned}$$

This model assigns a gamma processes to the common measure

$$a = (a((x_0, x_1]), \dots, a((x_m, x_{m+1}))),$$

that is,

$$\begin{aligned} \alpha((x_j, x_{j+1}]) | x &\sim_{\text{iid}} \text{Ga}(a_x((x_j, x_{j+1}]), \\ b_x((x_j, x_{j+1}))), \quad j &= 0, 1, \dots, m \end{aligned}$$

and independent Dirichlet processes to the experts' probability measures where α is each process's centering parameter.

As in the case of West's [27] model for nonparametric quantile forecasts, the model above assigns a reasonable continuous distribution (as an expert likelihood) for any finite number of probabilities. Consequently, one might expect such a model for random probability measures to induce a reasonable continuous distribution for the measure's corresponding quantiles (and vice versa). Interestingly though, this model does not induce a continuous distribution for its corresponding quantiles. A Dirichlet process used to describe the uncertainty in a random continuous distribution function induces a mixed finite-dimensional distribution for its corresponding quantiles—part discrete and part continuous distribution [31]. Thus, when aggregating nonparametric forecasts, a decision maker will want to identify which type of forecast—either quantile or probability—her experts will report. Once she knows the type of forecast, she can assess the appropriate expert likelihood.

SUMMARY

When a decision maker faces a decision, she may wish to consult others for their forecasts of an important uncertainty. Once she hears the experts' forecasts, the decision maker will look to combine them into a single coherent forecast. The principle behind the Bayesian approach to this problem is both simple and logically consistent. From a joint distribution of the quantity of interest and the experts' forecasts, calculate the conditional distribution of the quantity of interest given the experts' forecasts. This is the easy part. The difficult part is the assessment of the joint distribution.

The decision maker can break the assessment of this joint distribution into two parts: (i) assess her own prior distribution for the quantity of interest (which she would need in any case), and (ii) assess an expert likelihood, the conditional distribution of the experts' forecasts given the quantity of interest. The real challenge in Bayesian aggregation is the assessment of the expert likelihood. In the preceding sections, we saw this challenge decomposed into two more manageable assessment tasks: (i) judge each expert's discrimination ability, and (ii) judge the dependency between the experts' forecasts.

First, the assessment of an expert's discrimination ability amounts to the estimation of the dependency between the event of interest and the expert's forecast. Does the expert tend to report higher probabilities for the event when the event occurs and vice versa? Second, the assessment of the dependency between experts' forecasts amounts, in part, to an estimation of the degree to which the experts' information sources overlap. Do the experts share information and experiences in common? In the section titled "Model for a Binary Event and Two Overlapping Experts," we saw these two tasks come together in the context of forecasting a binary event. There, the decision maker's beliefs about these dependencies were affected by a shared inference model and some informational overlap. Similarly, in the section titled "Aggregation of Parametric Forecasts for a Continuous Quantity," we saw how these two assessment tasks played out in the context of forecasting a normal continuous quantity.

In the examples from the sections titled "Model for a Binary Event and Two Overlapping Experts" and "Aggregation of Parametric Forecasts for a Continuous Quantity," the aggregate distribution followed from shared beliefs about two explicit, small-scale, physical processes. The physics of these processes involved two experts who first collected a few pieces of exchangeable data, some of which overlapped, and then reported their updated beliefs. The decision maker deduced the aggregate distribution directly from the group's shared beliefs. In each case, a conjugate Bayesian inference model constituted their shared beliefs. We looked at the

most popular Bayesian inference models for a binary event and a continuous quantity: the beta-binomial model and the normal-normal model, respectively. Elsewhere, we showed some important extensions of these two models. These extensions used more free-form expert likelihoods. They anticipated hearing from experts with more refined and more complicated information sources—situations in which experts report multiple summary or nonparametric statistics.

In practice, a decision maker may reflect on the similarities the small-scale models presented in the section titled “Model for a Binary Event and Two Overlapping Experts” and “Aggregation of Parametric Forecasts for a Continuous Quantity,” share with actual large-scale problems. In the real world, expert information and experiences are more refined and messier than could be described with a small-scale model of exchangeable data. Nonetheless, a real-world expert likelihood will likely have the same statistical properties our small-scale expert likelihoods have. They will exhibit dependencies between forecasts and events. To assess these dependencies in the real world, our small-scale examples become powerful thought experiments. To assess expert discrimination, a decision maker might think about expert experience in terms of the quantity and quality of relevant data an expert has observed. To assess expert dependency, she might consider the degree to which there is overlap in the experts’ experiences.

In the end, to assess the dependencies between forecasts and events well is a skill best developed through repeated interactions with data. In environments where experts forecast events frequently, decision makers have the opportunity to collect valuable data on forecast and event outcomes. With enough data, a decision maker can build histograms (similar to Fig. 1 and 2) of forecasts given event outcomes. These histograms can informally guide the assessment of an expert likelihood. Alternatively, a decision maker may work directly with a hierarchical model, such as the one discussed in the section titled “Model for a General Discrete Event and Multiple Experts,” to update beliefs, given the historical data about

the hierarchical parameters in the model. These days, Bayesian simulation techniques and modern computing power make such inference possible [32]. On one level, this conclusion amounts to saying, let the data speak for themselves through our models.

BAYESIAN NETWORK CLASSIFIERS

MOISES GOLDSZMIDT
Microsoft Research, Mountain
View, California

The aim of classification is to assign objects, described in terms of their properties called *features*, to one of a finite number of discrete categories called *classes*. One example is deciding whether a disk will fail (stop working) within the next three days, (*class*), given a vector of measurements such as latency of reads/writes, size of the queues, number of retries, and number of reallocated sectors (*features*). Such a classifier can be used to initiate a disk replacement procedure in time without disruption of the service the disk is supporting. Another example is identifying a digit from the set 0 to 9, given information about the luminosity, color, and location of the pixels in a scan of a check. This capability can be used to automatically scan the amounts of checks at ATM machines or to automatically sort mail by recognizing zip codes. Yet another example is mapping documents to a predefined set of topics, based on the number of times each word in the dictionary appears in the document. This classifier is useful in a number of contexts including novelty detection in web news services.

Although classifiers can be built by hand through careful engineering, it makes sense to take advantage of the large amounts of data that are being collected today and build them automatically. Data about disk behavior are being regularly monitored in data centers. There are also large corpus of scanned checks and letters providing examples of digits in different contents; and to maintain search engines' working and news content flowing, there are numerous crawls of documents in the web which provide data for a classifier that detects novelty. This automation brings the additional benefit of making these classifiers adaptive to new data and behaviors.

The task of inducing classifiers in an automated fashion from data is the domain of pattern classification, statistics, and machine learning. It is one of the most successful tasks in these disciplines in the sense that (i) it is relatively well understood, and (ii) we have examples of high quality classifiers in various domains [1–5]. Consequently, there are a large number of techniques and algorithms, including decision trees [6], support vector machines [7], logistic regression [8], neural networks [5], and Bayesian network classifiers [9,10] to name a few.

Bayesian network classifiers work by representing a joint probability distribution model of the domain of interest. What make Bayesian network classifiers unique is that they arguably offer all of the following advantages:

1. Bayesian networks can combine both expert knowledge and statistical data [11]. Thus, it is possible to incorporate explicit expert knowledge about the domain into the classifier. For example, we can (both) explicitly encode and/or automatically discover relations about the (in)dependence among the features.
2. We can also encode knowledge about the probability distribution in the form of priors [12].
3. We can perform sound inference, both in fitting the probability distribution and when making a classification decision, even in those cases where some of the features are not measured [12,13].
4. As we have a complete distribution of the domain, we can make inferences regarding the most important features determining the class (decision) in each instance, and also make inferences regarding the importance of each of the features on expectation. This can be useful in data collection, in experimental design, and in justifying the rationale for decisions (see Cohen *et al.* [14] for an application where this was required).

5. We can also use the probability of any given decision (or the odds expressed in Equation (1)) as an indication of the confidence of the decision.

The justification for using Bayesian networks as classifiers is rooted in Bayesian decision theory (BDT) [1]. Consider the disk failure prediction task mentioned above. The class represented by C takes two values, c^1 for “the disk will fail within the next three days,” and c^0 for “the disk will not fail within the next three days.” The vector of features is denoted by $\mathbf{F}$. Let $P(C|\mathbf{F})$ denote the probability that the disk will or will not fail within the next three days. The uncertainty that gives rise to this probability comes from at least three factors: (i) we may not have all the necessary information in the feature vector $\mathbf{F}$ for the prediction (and, as it is usually the case, it may be impossible to directly measure such information); (ii) we may not have a precise notion of the functional relationship between the feature vector and the class; and (iii) there may be errors in the measurements of $\mathbf{F}$. The point of using a classifier is to take action or, in BDT terms, to make a decision. In our case, this may be to change the disk and use the period of three days to back up its contents in response to the signal from the classifier. Clearly, there is a cost for executing these actions: if the disk indeed fails in three days and we execute the back up and change the disk, we have the cost of a new disk and the resources expended in the backup; let us use r_{11} to denote this cost. However, if we do not replace the disk and we do not save the data, we will have the cost of the lost data, plus the fact that the service that depends on the disk will be unavailable. We use r_{10} to denote this cost. Let us use r_{00} for the cost of “doing nothing” (normal operation) and r_{01} for the unnecessary cost of backup plus replacement of a healthy disk. Invoking Bayes rule, and under the reasonable assumption that $r_{10} > r_{00}$, it is optimal (in the sense of minimizing risk) to decide to do nothing *if and only if*

$$\frac{p(\mathbf{F}|c^0)}{p(\mathbf{F}|c^1)} > \frac{(r_{01} - r_{11}) P(c^1)}{(r_{10} - r_{00}) P(c^0)}, \quad (1)$$

where p denotes a density function and P denotes probability. This essentially says that the optimal decision depends on the odds of how likely is the state of the monitored features under normal conditions (disk will not fail) versus the same state under the condition that the disk will fail. Note that the problem of inducing a classifier from data is now transformed to the problem of fitting the density (or probability) $p(\mathbf{F}|C)$ (as well as the terms relating to $P(C)$ on the right-hand side).

The rest of this article is organized as follows. We first formally introduce Bayesian networks in the section titled “Bayesian Networks,” and then in the section titled “Learning Bayesian Networks from Data,” we explain how they are induced automatically from data. We then address the learning of Bayesian network classifiers in the section titled “Bayesian Networks as Classifiers.” The section titled “Final Remarks” concludes this article with a set of final remarks.

BAYESIAN NETWORKS

A Bayesian network is an efficient encoding of a joint probability distribution defined over a set of random variables. The efficiency comes from explicitly representing relations of probabilistic independence, and providing algorithms to reason about these relations [15]. A Bayesian network for a set of random variables $\mathcal{X} = \{X_1, \dots, X_n\}$ consists of (i) a directed acyclic graph (DAG) $\mathcal{G}$ and (ii) a set of local probability distributions/densities p associated with each random variable. Together, these components define a unique joint probability distribution over $\mathcal{X}$. The nodes in the DAG are in one to one correspondence with the elements in the set $\mathcal{X}$. Let us use X_i to denote both the random variable and its corresponding node in $\mathcal{G}$. Let us further use Pa_i to denote the parents of node X_i in $\mathcal{G}$ (as well as the random variables corresponding to those parents). The structure of the DAG encodes the following statements about conditional independence: given the state of its parents Pa_i , X_i is conditionally independent of all its other nondescendants in the graph. Consequently, given the structure of

S , the joint probability distribution for $\mathcal{X}$ is given by

$$p(\mathcal{X}) = \prod_{i=1}^n p(X_i | Pa_i). \quad (2)$$

To illustrate the benefits of this factorization, we consider again the example of using a classifier to predict a disk failure. For the sake of this illustration, let us assume that each one of the variables $\{F_1, \dots, F_n\}$ is binary. A realistic scenario may be that these features are monitored signals in the disk and that they can be in one of the two states: *normal* or *abnormal*. In order to apply the classifier and make decisions, we need to compute the ratio in Equation (1). This implies that we need to have the values for the 2^n parameters that comprise $P(F_1, \dots, F_n | C)$.

Now assume that an “expert” builds a Bayesian network similar to the one in Fig. 1 for this domain. This network encodes the independence statement that each measurement F_i is independent of all the other measurements in the set $\{F_1, \dots, F_n\}$, given the value of the class. According to Equation (2), this translates into

$$p(F_1, \dots, F_n | C) = \prod_{i=1}^{i=n} p(F_i | C), \quad (3)$$

which requires only $2 \times n$ parameters. Using the Bayesian network in Fig. 1 we have gained exponential savings in terms of the parameterization of the domain!

Note that there is nothing that prevents us from representing further dependencies between features in $\mathbf{F}$. For example, our expert may determine (or we may gather evidence from data) that the signal that monitors the number of I/O retries (F_r) is correlated with the signal that monitors the length of the I/O queue (F_q). To include this dependence in the model, we add an edge from F_r to F_q in the Bayesian network, and then replace the term $p(F_q | C)$ with $p(F_q | F_r, C)$ in Equation (3). Note that this term now requires four parameters instead of two. More complex relationships can be added accordingly.

Having formally defined Bayesian networks and illustrated its benefits in terms

Figure 1. Naive Bayes network structure. The top node C represents the class and the nodes $F_1, \dots, F_n$ represent the features.

of the efficiency of representing a probability distribution, we concentrate on the methods by which we can induce one directly from data.

LEARNING BAYESIAN NETWORKS FROM DATA

Given the structure of the Bayesian network, such as the one in Fig. 1 and a data set of tuples $\langle C, F_1, \dots, F_n \rangle$, fitting the parameters of the conditional densities (probabilities) defined between a node and its parents in the network is conceptually a well-studied statistical problem of parameter estimation [12,16,17]. This problem can be approached in several ways. Two common and reasonable procedures are based on *maximum Likelihood* estimation and *Bayesian* estimation. The procedures are quite different conceptually, and the results obtained by these two procedures can be quite different as well. Maximum likelihood method considers the parameters as quantities whose values are fixed but unknown. The best estimate of the parameters is defined to be the one that maximizes the probability of obtaining the samples actually observed [16,18]. Bayesian methods view the parameters as random variables having some known *a priori* distribution. Observation of the samples converts this to an a posteriori density, thereby revising the true value of the parameters [17,19]. Let us go through the computations needed to fit the parameters of Fig. 1, for

both the maximum likelihood and Bayesian procedures. As an illustration, we take one of the terms, say $P(F_i|c^1)$, from Equation (3). We assume that we have a set of samples $S = \{f_i^1, f_i^2, \dots, f_i^j\}$, with the samples in S having been drawn independently according to the probability law $P(F_i|c^1)$. We assume that $P(F_i|c^1)$ has a known parametric form, and is therefore determined uniquely by the value of a parameter vector θ_i . In our example, given the fact that F_i can take one of the two values, it is reasonable to assume that the distribution is binomial and θ_i is a singleton. If we had assumed that the distribution is normal, then θ_i would be composed of a mean and a variance, which are the parameters of the normal distribution. We start with the approach based on maximum likelihood. To show the dependence of $P(F_i|c^1)$ on θ_i explicitly, we write $P_{\theta_i}(F_i|c^1)$. Our problem is to use the information provided by the samples to obtain good estimates for the unknown parameter θ_i . Let us take the standard assumption that the parameters for the different classes and the different $p(F_k|c^1)$ are functionally independent (namely, the samples do not provide any information to other parameters in the model). Then, since the samples were drawn independently we get that $p_{\theta_i}(S|c^1) = \prod p_{\theta_i}(f_i^k|c^1)$. As a function of θ_i , $p_{\theta_i}(S|c^1)$ is called the *likelihood* of θ_i with respect to the set of samples. The *maximum likelihood* estimate of θ_i is by definition the value $\hat{\theta}_i$ that maximizes $p_{\theta_i}(S|c^1)$. Intuitively, it corresponds to the value of θ_i that best agrees with the observed samples. If $p_{\theta_i}(S|c^1)$ is a well-behaved, differentiable function of θ_i , $\hat{\theta}_i$ is usually found by the standard methods of differential calculus.

The Bayesian methodology starts from the point of view that we should use all the information available in estimating $p(F_i|c^1)$, which in this case is the set of samples S . The goal then is to compute $p(F_i|S, c^1)$ which is as close as we can come in obtaining $p(F_i|c^1)$. Let us assume (as in the case of the maximum likelihood method) a specific functional parameterization of $p(F_i|c^1)$ given by θ_i . Then we compute $p(F_i|S, c^1)$ as an expectation over all possible values of the parameter θ_i

$$p(f_i|S, c^1) = \int p(f_i|\theta_i, c^1)p(\theta_i|S, c^1) d\theta \quad (4)$$

where the first term in the integral comes about because knowing θ_i renders f_i conditionally independent of the actual samples S . Note that θ_i is regarded as another random variable subject to a density/distribution $p(\theta|S)$. Thus, it can be explicitly represented as another node in the Bayesian network, where the assumptions of independence between parameters follow from the structure of the network. The computation of the integral in Equation (4) for a large set of common parameterizations and prior/posterior distributions on the parameters can be obtained in closed form [17]. Otherwise, Markov chain Monte Carlo techniques are used to estimate it [20].

It is beyond the scope of this article to describe in detail these two approaches, and their advantages and disadvantages. The answer to the question of which one is “correct” depends on the definition of the term “correct.” All estimators will have different formal properties and the estimator to be selected will depend on the task at hand. For the classification task, we may compare different estimates on the basis of the error rate of the resulting model, namely, the rate by which the classifier predicts the correct class given an agreed upon data set D to be used as a benchmark (see the section titled “Final Remarks”). It is important to note two things. First, in spite of having *Bayesian* in the name, Bayesian networks are not tied to any particular way of estimating the parameters and the user can select the method that is more convenient for the task at hand. Second, under the assumptions of independence between the parameters outlined above, the learning task decomposes following the structure of the network.

At this point, we know how to learn the “probabilities” given the structure of the network. Let us consider the problem of learning both the structure and probabilities given a data set of tuples $\langle C, F_1, \dots, F_n \rangle$. There are basically three approaches to do this. The first one takes a purely Bayesian approach. Note that, in principle, we can introduce a random variable G encoding possible graph structures and extend Equation (4) with the appropriate terms to compute the expectation over the set of possible structures G .

There are many practical problems, given the combinatorial nature of the space of possible structures G , with computing some of the required averages (see Friedman and Koller [21] for an approach based on Markov chain Monte Carlo techniques). More popular approaches treat this learning task as a combinatorial search problem, guided by a score, which in turn is computed using a maximum likelihood, maximum a posteriori, or Bayesian estimation techniques [11,12]. Thus, given a particular structure G' , the parameters are estimated using statistical techniques. Then, a score on the complete network is computed and used to select the next possible network structure G' . Different criteria and search methods are studied extensively in Chickering [22] and references therein. The third approach takes the definition of independence encoded in the structure as a starting point, and relies on statistical independence testing between the different random variables to discover the structure of the network [23,24]. More information about the theory and principles behind graphical models, inference, and learning in a text-book form can be found in Koller and Friedman [25]. The main point in the previous paragraph is that the induction of a network structure is formally a hard combinatorial problem [26], and as we see below, it has consequences for the classification task.

BAYESIAN NETWORKS AS CLASSIFIERS

One of the most important parts of the classification process is the evaluation of the performance of a given classifier. A natural and very common way to do this is based on estimating the *error rate* of a classifier on a set of instances taken from a data set D . The classifier predicts the class of each instance: if it is correct, it qualifies as a success; if not, it is an error. The error rate is just the proportion of errors made over a set of trial instances. This particular error rate is known as the 0–1 loss error rate, and it essentially entails that $r_{00} = r_{11} = 0$ and $r_{01} = r_{10} = 1$ in Equation (1).

Getting back to the automated learning of a Bayesian network classifier from data.

Based on the discussion above, a reasonable strategy consists of using the methods in the previous section to fit the distribution/density $p(\mathbf{F}|C)$, and then use Equation (1) to make decisions. In Friedman *et al.* [9] the author of this article and colleagues applied such a strategy to 25 data sets that were considered to be benchmarks at that time. We then compared the error rate of the Bayesian network classifiers thus created to ones that have the basic structure as displayed in Fig. 1. A classifier that follows that structure is called a *Naive Bayes classifier* (NBC), because it assumes that each feature F_i is independent of the rest of the features in $\mathbf{F}$, given the class C . Our original hypothesis when we started that experiment was to use the NBC as a baseline. To our surprise, we found the performance of the NBC to be superior (on average) to that of classifiers with general Bayesian network structure. We first examine the main reasons for these results, and then review on a strategy to improve on the NBC.

Most of the challenges of inducing good classifiers have as root the unavoidable problem that the data at hand is finite. All estimators provide strong guarantees of convergence to the actual distribution in the data as the number of samples available tend to infinity. This is hardly the case in practice. Moreover, the demand for a larger number of samples grows exponentially with the dimensionality of the feature space. This limitation is related to what Bellman called *the curse of dimensionality* [27].

With this in mind, we remind the reader that even though we are following the dictates of BDT when making a decision based on a Bayesian network classifier using Equation (1), we cannot guarantee the optimality of the error rate as we do not have the distribution p at the time of applying this rule; we have an *estimate* $\hat{p}$ of the required distribution.

The error in the estimate of $\hat{p}$ can come from multiple sources. There are of course issues with selecting the wrong parameterization (or functional form) when estimating the parameters of p . Most importantly, recall that the induction of the structure of the network requires a search process over a

really large combinatorial space. In addition, there are large sets of networks that are equivalent with respect to the statements of independence that they encode, yet they present different graph structures [28]. Thus, it may be the case that during the automated fitting of $p(F_1, \dots, F_n, C)$, the algorithms perform a really good job in terms of the score selected to evaluate the network because it is fitting the parameters of maximum likelihood of a particular subspace of the joint distribution, while ignoring more important subspaces that are more relevant for the error rate. One way to address this problem is based on the following considerations. By rearranging the terms of Equation (1), and assuming the 0-1 loss error rate, we note that we are still maintaining the optimality in our decision if we use the following rule: decide c^0 if and only if $\frac{p(c^0|f_1, \dots, f_n)}{p(c^1|f_1, \dots, f_n)} > 1$. This begs the following question: why not fit $p(C|F_1, \dots, F_n)$ directly? Indeed this is what logistic regression does [8]. The trade-off is that one misses the advantages of having a full Bayesian network classifier model (stated in the introduction).

There is a large literature explaining the success of the NBC given its strong assumption of independence among features, even in domains where this assumption does not hold [1,10,29]. The analysis is subtle and nontrivial. Here, we provide some intuition and recommend the readers to the papers just cited for the formalization of these arguments. First, we remark that because it is fitting components of the form $p(F_i|C)$ it is guaranteed to maintain the focus of the statistical fitting process on the relationship between the features and the class. Thus, it does not run the risk of falling into an “uninteresting” region of the joint density between features, during the search for structure mentioned in the previous paragraph. Second, we note that it is very robust to the inherent variance in the data, and even though it does not fit a precise probability of the domain, it is able to find a good separating surface for the data. We illustrate this point following an example taken from Duda and Hart [1]. Consider fitting a polynomial to a set of points. Fitting a straight line may not follow the exact location of all the points; yet, it

will find the (linear) trend in the data and it will be robust to noise and general variance in the data samples. One would have to have a large set of points in order to attempt a larger degree polynomial, and this fitting would be more sensitive to variations and noise. Similarly, the NBC will find a highly biased separation between the classes (given by its fixed structure, which is related to a linear separator [1]), but it will be robust to noise, and unimportant variations in the (always) limited sample of data. Because of the high bias, this classifier does not produce calibrated probabilities on the classes given a random sample, and thus the probabilistic output should be handled with care [30]. The terms “bias” and “variance” have been introduced in a very informal fashion, yet they constitute mathematical decompositions of various error measures. Formal analyses can be found in Domingos and Pazzani [10] and Friedman [31].

A well-known approach for improving the performance of the NBC is based on keeping the general structure of the naive Bayes, but enhancing its modeling of dependencies between the features by allowing a limited set of dependencies between them. The idea is to maintain the desirable properties of the NBC, namely, low variance, and no search for structure, while improving on the modeling assumptions of independence. One such approach is called TAN (tree augmented naive Bayes) [9], and it is based on an algorithm proposed in Chow and Liu [32]. This algorithm finds a tree of dependencies among a set of random variables in polynomial time. This tree is guaranteed to be the tree of maximum likelihood with respect to the data among all possible trees. The resulting structure of the classifier is depicted in Fig. 2. It was shown empirically, on the relevant set of benchmarks at that time, that (on average) the TAN classifier performs better than the NBC [9]. Since then, there has been a large number of proposals for Bayesian network classifiers exploring different trade-off and benefits, improving on TAN and NBC, and also applying these in different domains and contexts. TAN and NBC remain extremely popular among both researchers and practitioners.

Figure 2. The combination of a naive Bayes structure (a) with a tree dependency structure on the features (b) yields a tree augmented naive Bayes (TAN) network structure (c).

Some references are given in the section titled “Final Remarks,” yet the reader is encouraged to look on-line for the latest approaches and improvements.

FINAL REMARKS

Besides defining an error rate, the evaluation and comparisons of different classifiers require the emphasize of such rate. In the selection of both the proper criteria for evaluation and the right methodology for estimation, the field of pattern classification borrows heavily from statistics. A good general introductory book that focuses on the pattern classification task is Witten and Frank [33]. More in-depth coverage of

topics and issues such as hypothesis testing, cross validation, Receiver operating characteristic (ROC) curves, and model selection can be found in Hastie *et al.* [3], Wasserman, [16], Efron and Tibshirani [34] Demšar [35], Kohavi, [36], and Lachiche, [37].

The induction and proper evaluation of a classifier are just two of the tasks involved in the enterprise of actually applying the classifier in a given domain. There are the data collection task and the feature extraction task. For example, once the raw data about the sizes of the queues of ten thousand disks in the data center are collected, we might decide to compute the median and use the deviation of the median as a feature for our classifier. There is also feature transformation, which may involve normalization

and other mathematical operations on the features that may include the transformation of the whole space using kernels [2,4,7]. Other tasks include dimensionality reduction and feature selection, which are essentially about eliminating features that are irrelevant or may introduce noise in the induction process [1,3].

With the continuous increase in computational power, the availability of data, and the continuous improvement in data collection and storage techniques, there is a strong interest in methods and techniques for automatically extracting actionable information from data. Classifiers play a crucial role in this endeavor, and Bayesian network classifiers in particular are used extensively both in academia and in a wide range of industrial applications and domains. The reasons stem from the ease of implementation, interpretability of the resulting model, the transparency by which users can understand and analyze their performance, and the relative ease to extend the models in several ways and adapt them to different domains. All of these factors are derived from the fundamental representational properties of Bayesian networks, which are listed in the introduction. At this point, it should be clear that a classifier can be induced from data, starting from a given structure, or from a partial structure, and the same applies to the specification of the parameters (and in the case of Bayesian statistics, from priors on all these). This covers the first two advantages given in the introduction. The last three advantages stem from the fact that a Bayesian network classifier is a complete distribution of the domain (classes and features). So, the computation of one of the variables in terms of the other is a matter of applying the well-known rules of probability theory (including those cases where the data contain missing values [12,13]).

A complete list of applications and domains where Bayesian network classifiers play a crucial role is beyond the scope of this article. We will be content to mention just a few for illustration purposes. Early work on automated spam filters, for example, relied on naive Bayes [38]; more recent work in the domain of natural language processing is

described in Peng *et al.* [39], which augments the basic NBC with statistical language models for diverse tasks such as authorship attribution, text genre classification, and topic detection (in several languages). Applications to computer systems (similar to the example used in this article) are described in Cohen *et al.* [14] and Moore and Zuey [40]. In Cohen *et al.* [14], the authors use the modeling capabilities of the Bayesian network classifiers to point to likely indicators of performance problems for diagnosis. In Moore and Zuey [40], the NBC is used to automatically classify traffic in computer networks for security monitoring, accounting, and quality of service. There are plenty of examples in other domains such as biology and bioinformatics [41–43], medicine [44,45], computer vision [46–48], and finance [49,50]. This brief enumeration does not pretend to be either exhaustive or authoritative. It is simply designed to show the breadth of applications and is focused on publications in the last six years to highlight the freshness of the techniques. The reader is advised to consult many of the available on-line sources when looking for a particular domain and/or application.

BEHAVIORAL ECONOMICS AND GAME THEORY

MIGUEL A. COSTA-GOMES
University of Aberdeen Business
School, Aberdeen, UK

Game theory is a powerful tool to analyze interactions among a small number of agents. The main goal of game theory is to make predictions about which strategies agents play. Its main solution or prediction concept is Nash equilibrium. A combination of players' strategies (one for each player) is a Nash equilibrium if each player's strategy is optimal in the sense of maximizing her expected payoff, given the others' strategies. An example helps to illustrate this concept of equilibrium.

Consider a static (or simultaneous-move) game described in detail in Costa-Gomes and Weizsäcker [1]. It is a two-person three-by-three payoff matrix game (Fig. 1). The numbers in each cell denote the numbers of points (referred to as *payoffs*) that each of the two players earns in the cell's corresponding outcome.

In this game, the only Nash equilibrium is {B, R} because it is the only combination of actions in which each of the players plays the strategy that earns her the most points given the other player's strategy. Thus, none of the players can increase her number of points by changing her strategy given the other's strategy.

However, the concept of Nash equilibrium is sometimes a poor predictor of human behavior, as documented by Costa-Gomes and Weizsäcker [1], among many others. They asked a group of human subjects who were assigned the roles of Row and Column to play this game once. Costa-Gomes and Weizsäcker observed that out of 66 Row subjects, although 38 played B, their equilibrium action, 7 played T and 21 played M. Only 13 out of 62 Column subjects played their equilibrium action, R, and 24 played L while 25 of them played M.

The purpose of this article is to briefly introduce the modeling approaches that have been proposed to explain why behavior in games deviates from equilibrium.

The search for explanations has relied to a great extent on *behavioral economics*. Behavioral economics acknowledges the fact that rationality is a very strong assumption when modeling people's decisions and relaxes it by paying close attention to a variety of empirically based concepts in psychology. The use of the behavioral economics approach to understand how people play games has resulted in a new variety of game theory, which many refer to as *behavioral game theory*, a term coined by Camerer [2,3]. Although, behavioral game theory's mathematical apparatus is firmly grounded in game theoretical concepts that are used to describe and analyze games such as utility, beliefs, and decision-theoretic rationality, it departs from it by selectively incorporating different ideas from psychology that give rise to different kinds of explanations for the observed deviations from equilibrium.

It is important to note that most of the empirical evidence on the limitations of equilibrium in describing behavior is gathered from studies where people, typically university students, take on the roles of players in a game, and receive monetary payments that are directly related to the point payoffs they earn in the games they play. Such studies are known as *economics experiments*, a term used to describe the use of experimental methods to study situations with economic content. Economics experiments allow for tests of the behavioral predictions of equilibrium as long as one is willing to assume that human subjects decide according to the preferences of the players in the game that is described to them. In other words, tests are possible as long as the use of monetary rewards leads to the control of subjects' preferences. Experiments are useful because by changing the game being played in different ways it is possible to observe and document systematic patterns in behavior.

This article briefly summarizes the broadly defined categories of behavioral explanations and their links to ideas in psychology, whenever appropriate.

GAME THEORETIC REASONING

To better understand why people do not always play equilibrium strategies, one has to explore the logic that underpins game theoretic reasoning, and why in some games one has to use concepts that go beyond equilibrium to narrow down predictions about play.

To do this, we revisit the game described above and present an example of a dynamic (sequential) game along with some play data.

How does one identify the equilibrium (or equilibria, in case there is more than one) in a game? There are different ways of doing this.

One way is to consider each of the possible combinations of strategies and test whether any of the players would want to play something else given the others' strategies so as to increase her payoff. An equilibrium is found when none of the players wants to change her strategy given the others' strategies, that is, when we end up with the same combination of actions that we started with. Another way is known as *best-response dynamics*. This procedure is easy to describe in a game involving two players. One starts from a hypothetical strategy for one of the players and then determines the other player's best-response, that is, the action of the other player that maximizes her payoff. This procedure is iterated until players' best-responses stop changing.

Both of these procedures illustrate the circularity logic of equilibrium. Although equilibrium is a beautiful logically consistent concept, its circularity makes it an unnatural cognitive process.

In some games it is possible to use a different procedure to find a game's equilibrium, or to simply narrow down the set of strategies for each player that can be part of an equilibrium. Such a procedure is known as *iterated dominance*, or *iterated elimination* of strictly dominated strategies. A player's strategy is dominated by another of her strategies if it yields a strictly lower payoff for each of the other player's strategies. A rational player does not play a dominated strategy, and therefore it can be disregarded or eliminated. Iterated dominance is the process of elimination of dominated strategies of all players in an iterative manner. The game in Fig. 1 is used to illustrate iterated dominance and its logic.

In this game, M is dominated by T for the Row player, because she can earn more points by choosing the latter strategy over the former one, regardless of the Column's choice. A rational Row player will not choose M. By assuming that Column knows that Row is rational, we can conclude that a rational Column player will not choose M or L herself, because each earns her fewer points than R, independently of whether Row plays T or B. If we further assume that Row knows both that Column knows that Row is rational and that Column is rational, Row can iterate the deletion of conditionally dominated strategies one step further, and conclude that B will earn

him more points than T, given that Column plays R. In this game the use of iterated dominance leads to a unique strategy for each of the players, B and R, which together constitute the Nash equilibrium strategy profile of the game. This example shows how iterated dominance is related to assumptions about players' rationality, their knowledge of each other's rationality, and so forth. This example illustrates the delicate nature of iterated dominance, and that it breaks down when any of its assumptions does not hold.

Now, an example of a dynamic game to show that sometimes game theory needs to go beyond the idea of equilibrium to produce more precise predictions is presented.

The dynamic game is a three-stage alternating offers-bargaining game presented in Johnson *et al.* [4] and depicted in Fig. 2. In this game, two players have to agree on how to divide an amount of money that shrinks by half from one stage to the next in case of no agreement. The first mover is player 1 who makes an offer, x_1 , to player 2, an amount between \$0 and \$5, who decides whether to accept or reject it. If player 2 accepts the offer, the game ends with her earning x_1 and player 1 ($5 - x_1$). Otherwise, after her rejection, she gets her turn to make an offer, x_2 , to player 1, an amount between \$0 and \$2.5, who decides whether to accept or reject it. Acceptance by player 1 leads to earnings of x_2 for player 1 and ($2.5 - x_2$) for player 2. Rejection by player 1 earns him the right

to make the final offer, x_3 . The game ends with either acceptance, with players 1 and 2 earning $(1.25 - x_3)$ and x_3 , respectively, or rejection that earns both players \$0.

Because this game has many equilibria, a more precise prediction requires one or some equilibria to be selected over the others. Thus, game theory has to go beyond the concept of equilibrium. In sequential games where players observe each other's moves, the concept used is backward induction. The analysis of the game starts at the last stage and proceeds backward to the first stage. At each stage of the procedure, the player who has to choose plays the action that gives her the highest payoff.

The working of the backward induction is illustrated here by applying it to this game. In the last stage, player 2 is indifferent between accepting or rejecting \$0 and accepts \$0.01 rather than rejecting it and earning \$0. Thus, player 1 offers \$0 (when player 1 accepts \$0) or \$0.01 (when player 1 rejects \$0) to player 2 in the third stage which she accepts, and keeps \$1.24 or \$1.25 to himself. Since player 1 is guaranteed \$1.24 or \$1.25 in the last stage, in the second stage player 2 offers between \$1.24 and \$1.26 to player 1, which he accepts. Player 2 keeps between \$1.24 and \$1.26 to herself. Consequently, in the first stage player 1 offers an amount between \$1.24 to \$1.27 to player 2, which she accepts, keeping between \$3.73 and \$3.76 to himself.

Figure 2. Johnson, Camerer, Sen, and Rymon's three-stage alternating-offers bargaining game.

However, these predictions differ from how people play this game. In one of the experimental treatments reported in Johnson *et al.* [4], the average opening offer is \$2.11, and player 2 rejects offers 10.8% of the time. In the second round, player 2 makes disadvantageous offers (that is offers that earn her less than the amount offered by player 1 in the first stage) 85% of the time. Player 1 rejects 21% of the second stage offers, resulting in him making a final offer that is rejected by player 2 two-thirds of the time.

In short, the data shows that backward induction equilibria offers are observed infrequently and that in many games players' strictly positive offers in all three stages are rejected. But even in a Nash equilibrium not necessarily consistent with backward induction, one of the three offers has to be an equilibrium one, which is then accepted. These and other similar results in sequential games challenge equilibrium and refined versions of it such as backward induction as good predictors of play.

WHAT IF NOT EQUILIBRIUM?

Broadly defined, there are three nonmutually exclusive ways to explain behavioral deviations from equilibrium. One of them links nonequilibrium play to the nonstrategic elements of the decision process, often using decision-theoretic models of bounded rationality. Another interprets the deviations as the manifestation of people's bounded rationality in analyzing the strategic elements of the decision situation. Finally, a third one relies on the idea that players' preferences go beyond the material payoffs they earn in the game. We now provide brief descriptions of the different approaches sometimes using empirical evidence from the games discussed above to substantiate them.

Models of Play When Playing Nature Rather than Others

One class of explanations puts aside the strategic aspect of the players' interaction and approaches the player's decision process as if she faces a dummy player (referred as Nature) whose actions are given by a

known probability distribution, because no attempt is made to explain how the player arrives at that probability distribution that represents the beliefs she holds about the play of her opponents. Mostly, these explanations revolve around departures of the standard model of a decision maker (a subjective expected utility maximizer with a certain attitude toward risk). Under the assumption that a player's utility is a function of her own monetary earnings (which add to her wealth) and that she is risk-neutral, this model predicts that a subject plays the action or strategy that maximizes her expected monetary earnings given her probabilistic belief about the actions of her opponent. Therefore, when only actions (but not beliefs) are observed, failures of compliance with subjective expected utility maximization in a game are hard to detect, except for the play of dominated actions. Such limitation has prompted researchers to resort to the elicitation of beliefs to gather data to complement action data in order to better document failures of subjective expected utility maximization in games. For example, Costa-Gomes and Weizsäcker [1] analyze actions and stated beliefs jointly, finding that in the game above and another 13 similar games more than one-third of the time subjects do not play the action that maximizes their expected monetary earnings given their stated beliefs. In the context of Costa-Gomes and Weizsäcker [1]'s experimental design the observed inconsistencies between actions and stated beliefs are a rejection of the joint hypothesis that a subject is risk-neutral and expected utility maximizer. However, as stated by Costa-Gomes and Weizsäcker [1], stated beliefs cannot be taken at their face value because elicitation mechanisms are truth revealing only under particular assumptions; they are responses to the monetary incentives in experiments and therefore when reporting other than the true belief, a subject loses money in the same manner as he loses by not playing the action that maximizes its subjective expected utility; they might not be accessible at all because some subjects might not hold beliefs. Hence, although the evidence generated by such inconsistencies prompts researchers to search for models that can

rationalize behavior, the net has to be cast wide. We now briefly describe some of those attempts.

A simple explanation questions the assumption that subjects are risk-neutral even though they are expected money maximizers. Although equilibria in pure strategies are insensitive to players' attitudes toward risk, risk aversion can explain the deviations from the unique mixed-strategy equilibrium in generalized matching pennies games, as shown by Goeree *et al.* [5]

A different dimension of the decision process deals with the possibility that subjects in experiments exhibit ambiguity in the sense that they cannot assign probabilities to the possible outcomes of the random variable that describes the choice of their opponent. Ambiguity makes the probabilities that subjects assign to the play of their opponents to not necessarily sum up to one. Instead, they can add up to less than one in the case of ambiguity aversion or to more than one in the case of ambiguity loving (see for example, the formulation of ambiguity proposed by Schmeidler [6]). Camerer and Karjalainen [7] find that a considerable fraction of their subjects exhibit ambiguity aversion in simultaneous-move games.

Prospect theory, a concept coined by cognitive psychologists Kahneman and Tversky [8] has also been used to explain game playing by experimental subjects. Its core ideas are that individuals treat gains and losses differently and weigh probabilities in a nonlinear manner. In this theory, an individual evaluates outcomes in relation to a reference point that reflects her aspiration level which could arise out of adaptation or experience. Thus, the individual assigns values to the monetary payoffs in a way that reflects their position in relation to the reference point. In addition, while in the loss domain the marginal utility increases as the outcome improves, in the gain domain the marginal utility decreases. The individual is risk-averse above the reference point, but risk-loving below it. Furthermore, values are assigned in a way that the positive value of a gain is smaller (and according to many estimates not far from a half) than the absolute value of an equal sized loss, a feature known

as *loss aversion*. Besides evaluating outcomes the individual also weighs probabilities. The effect of probability weighting on individuals is that they may end up perceiving them differently from their objective values. The empirical evidence suggests that people overweight small probabilities but underweight large probabilities. Prelec [9] provides an axiomatic derivation of a parametric weighting function. Goeree *et al.* [5] combine nonlinear probability weighting with risk aversion although not considering the other features of prospect theory in their data analysis of generalized matching pennies games. However, they find that the weighting function inferred from the data does not exhibit the "inverted" S-shape the theory posits it has.

Boundedly Rational Models of Strategic Thinking

In a different class of models special attention is paid to the modeling of players' beliefs about the play of their opponents. The different specifications of players' beliefs reflect the varying degrees to which players' decisions take into account the incentives of their opponents. Although in some models beliefs are tied down to equilibrium reasoning, in others they simply reflect players' boundedly rational strategic thinking, or as ascribed by them to their opponents. In addition, very often these models consider a nonstrategic dimension of bounded rationality as they consider that the act of best-responding is itself subject to errors.

One of the leading models is McKelvey and Palfrey's [10] quantal response equilibrium (henceforth QRE). Its boundedly rational interpretation results in a generalization of the concept of Nash equilibrium by replacing best-response behavior with better-responding behavior. While in a Nash equilibrium each player always plays an action that earns her the highest expected payoff given the behavior of the other players, in a QRE, players play actions with higher expected payoffs more frequently than actions with lower expected payoffs. That is, in the latter concept an expected payoff maximizing action is not always played, but is played more frequently than actions with lower expected payoffs. The

rationale for it is that people are imperfect expected utility maximizers because they make mistakes, which are more frequent the smaller their costs are. In addition, in a QRE, players model their opponents as being exactly as imprecise decision makers as they themselves are, and take this into account when computing the expected utility of their actions; the same is true of their opponents. Although, the theoretical construct is relatively general, the choice specification that embodies mistakes that is mostly used to fit the model to the data is the logit choice rule, which results in the concept of logit quantal response equilibrium.

Weizsäcker [11] adapts QRE by allowing players to be wrong about the level of imprecision of others, and calls it asymmetric QRE. Although players' reasoning is circular as required by the equilibrium, because they are allowed to be wrong about the level of imprecision of others, their beliefs about their opponents' behavior can be incorrect.

Interestingly, the QRE concept lends itself to a different interpretation. Here, the players are not boundedly rational, but are playing a Bayes–Nash equilibrium of a game different from the one that is represented by the material payoffs, because of perturbations to such payoffs that can be seen as accounting for nonpecuniary payoff considerations, and which can arise for many reasons such as mood effects, and so on. The concept of QRE has been extended to dynamic games by McKelvey and Palfrey [12].

A different strand of the literature posits that people use rules of thumb that are not cognitively taxing. In general, these rules dispense with the circularity of equilibrium reasoning because players' models of their opponents make them redundant. In these models, players are self-interested material payoff maximizers and hold beliefs about their opponents which emerge out of the rule of thumb they follow. Its leading example is what is known as *level- k thinking*, which is a model of iterated best-responses usually anchored on a prior belief. Although in many applications the anchoring belief is the uniform prior, as suggested by the intuitive cognitive principle of insufficient reason (with the justification that the player is either

unable to put herself in the shoes of her opponent or does not know that her opponent is rational at all), in general, the anchoring belief captures a player's instinctive reaction on how to play the game. A level-1 player is someone who best responds to a uniform random opponent called level-0, while a level-2 player best responds to an opponent who is best-responding to someone who randomizes uniformly, that is, it best responds to a level-1 player, and so forth. Low level- k thinking can mimic equilibrium when the game is dominance solvable in a few steps. For example, in the game in Fig. 1, a level-3 Row player or higher plays B, the equilibrium action, while a level-2 or higher Column player plays the equilibrium action R. Different versions of the level- k model take different views on how a level- k player models his opponents. While some, such as Costa-Gomes *et al.* [13] and Costa-Gomes and Crawford [14], consider that a level- k models her opponents as being level $k - 1$ (like Nagel's [15] nonstructural level- k model), thus opting for simplicity of the rule of thumb, others such as Stahl and Wilson [16,17] and Camerer *et al.* [18] consider that she believes that her opponents are heterogeneous with some behaving as level-0, others as level-1, and so forth, up to level $k - 1$, according to the conditional relative frequencies of the different levels or types given that she is level- k . Consequently, the calculation of level k 's best-response cannot be reduced to the outcome of k iterated best-responses to a uniform prior. Although the latter view of the level- k model makes it a more cognitively taxing model, it usually moves the behavior of higher levels closer to the aggregate behavior of the lower levels in the game being played.

The typical experiment has each subject playing a series of games with her sequence of decisions used to identify the rule of thumb, if any, that she uses when playing novel games. The usefulness of the basic level- k model is confirmed by data gathered using information search tracking methods that shed light on the cognitive processes subjects use while making decisions. In fact, level- k rules have been compared to other rules of thumb such as iterated deletion of dominated strategies, or D- k rules, which are more closely aligned

with game theoretic reasoning [13,14]. Subjects' decisions and information search when analyzed separately or jointly reveal that D- k rules are not good descriptors of behavior.

The level- k model has been extended to games of incomplete information by Crawford and Iriberri [19], who use it to explain behavior in private-value and common-value actions. Its extension to dynamic games raises lot of issues (e.g., how to model the fact that a fraction of subjects do not even look up the final-stage elements of the game such as payoffs before they initiate play, as shown in Johnson *et al.* [4]) and although no general way of doing so has yet emerged, Crawford [20] and Östling and Ellingsen [21] use it to analyze communication in games.

Models of Nonpecuniary Payoffs

There is a class of models that posits that material payoffs do not fully capture subjects' preferences over outcomes. Its core idea is that elements of the game other than a subject's material payoffs have an effect on her preferences in a systematic rather than a random manner. Therefore, modeling such effects is a worthwhile endeavor as it can help to predict behavior in novel games. In other words, by uncovering how the different features of a game influence subjects' preferences, control of subjects' preferences can still be achieved, even if it is not solely driven by own material payoffs.

Nonpecuniary payoff considerations can influence subjects' preferences over the game's outcomes in different ways: the material payoffs of a player's opponents in an outcome can influence her payoff in that outcome; a player's payoff in an outcome can be a function of procedural concerns; a player's payoff in an outcome can be a function of her own or her opponents' material payoffs in other outcomes; a player's payoff can depend on her belief about the actions chosen by her opponents; a player's payoff can also depend on high order beliefs such as what she believes about what her opponent believes she is going to play. Sobel [22] provides a description and comparison of these different approaches.

The class of outcome-based models of preferences defines a player's utility or payoff

in an outcome as a function of the player's own material payoff and some or all of the other players' material payoffs in that outcome. Models such as those of Fehr and Schmidt [23] and Bolton and Ockenfels [24] explore the idea that people are averse to the inequality of players' material payoffs, both when they are at an advantage and when they are at a disadvantage compared to others. These two models differ on players' perceptions of inequality: according to Fehr and Schmidt [23] a player has a self-centered view of inequality and compares her material payoff with those of all the other players, while according to Bolton and Ockenfels [24] a player compares her material payoff with the average material payoff of the other players. Charness and Rabin [25] add efficiency considerations as well as concerns for the less well-off individual (giving rise to maximin preferences) to inequality aversion.

A variety of experiments have revealed that aggregate behavior is sensitive to all these concerns as well as to others. But, within a particular game one or a few concerns tend to be more salient than the others, as an individual's perception of what is fair is situation-dependent. Most of the clearer existing evidence comes from one-person games, that is, situations where one player chooses one of several allocations of material payoffs for herself and the others.

Another approach takes into consideration that a player's preferences over outcomes are context-dependent. While in outcome-based models a player derives the same utility in two outcomes with the same profiles of players' material payoffs; they can be different when preferences are context-dependent because they can be influenced by the player's or her opponents' material payoffs in other outcomes. Striking evidence for such preferences is provided in Falk *et al.* [26]. This study compares two games that are identical to each other except that one of them has two additional outcomes. They find that subjects' aggregate choices over a pair of outcomes common to the two games depend on whether or not the game has the two additional outcomes. An intuitive and appealing example of context-dependent preferences is provided

by models that extend outcome-based models by allowing players' preferences in outcomes to depend on procedural concerns. In such models a player's preferences over two outcomes depend on the procedure that generates the situation where the player has to choose between them. Bolton *et al.* [27] provide evidence that a player is more willing to accept outcomes where she receives considerably less than her opponent if the procedure that puts her in that choice situation is unbiased, in the sense that it could put her opponent in the same exact situation with the same probability. Bolton *et al.* [27] proposes an extension of the model of inequality aversion [24] that makes players' utilities a function of the procedure.

A different class of models assumes that players' beliefs about actions or beliefs about beliefs about actions (i.e., high order beliefs) influence a player's utility. For example, a player's belief about her opponent's action can be interpreted by the player as the intention of the other toward her, namely her perception of how kind or unkind he is being toward her. On the other hand, an emotion such as guilt is better modeled through a second order belief, as explained by Battigalli and Dufwenberg [28], since guilt is an emotion related to what a player believes about what her opponent believes he will play. Although a variety of emotions can be incorporated into players' utility functions, reciprocity has been the main one modeled by researchers. In addition, conformance to norms and other forms of socially driven behavior can be usefully incorporated into players' payoffs via beliefs. The framework that has been used to do all the above is psychological game theory, which has been reinvigorated by Battigalli and Dufwenberg [28], who have developed it further, but who have also highlighted its current limitations.

MODELING ADAPTIVE DYNAMICS

Games are often played repeatedly. Although in many games play converges to equilibrium, in many others deviations, although not necessarily stable, never go away. To comprehend this diversity in behavior, researchers

have put forward models that try to capture how people adjust their behavior from one period to the next. This literature is usually referred to as the *learning in games literature*, thus effectively borrowing the term from game theoretic formal models of learning how to play equilibria. Because it is impossible to infer from the data that people are learning to play equilibria, I use the term adaptive dynamics to refer to this literature. The different generations of adaptive dynamics models show how insights from psychology have helped shape its progress.

One strand of model is belief-based. The core idea of this strand is that a player forms beliefs about the actions she expects her opponents to play in the next period on the basis of what they played in the past. She then plays the action with the highest expected payoff. Models differ from each other according to the weights attached to different periods of past play. The weights determine a player's belief about her opponent's play in the current period. In *fictitious play*, a player's distant and recent past play are weighed equally. As a result, beliefs are given by the opponent's empirical relative frequency of past play. Cheung and Friedman's [29] model of empirically weighted beliefs is a more flexible approach as the weights attached to an opponent's past play decrease exponentially with the number of periods that have elapsed, thus conforming to the psychological insight of recency, that is, the recent past counts more than the distant past. A different approach is proposed by Crawford [30] who suggests that players adjust their choice toward what would have been optimal for the last observation of the outcome with the adjustment fluctuating up and down as play proceeds. In all these models a player's behavior in a period is uniquely determined by the history of play of her opponents. An alternative class of belief-based model receives the label of *sophisticated learning*, because it has a forward flavor to it, as a player takes into consideration how her future play will influence the play of her opponents in future periods.

A different class of learning model borrows heavily from insights in psychology, and it is known as *reinforcement-learning* [31].

The main insight used is that experienced rewards are central to decision making. Therefore, experienced payoffs (the payoff a player earns by playing an action) rather than counterfactual payoffs (the payoff a player could have earned by playing a different action), are the key variables in determining how players adjust their behavior. Strategies played are reinforced, while strategies not played are not. Reinforcements can cumulate or be averaged, and define propensities that determine the probabilities with which the different strategies are played. Enriched versions of reinforcement-learning incorporate other insights from psychology: people evaluate experienced payoffs in relation to reference points or aspiration levels (which are the product of experience themselves, and hence vary), thus implying that reinforcements are defined in relation to a reference point; experimentation, that is, people now and then like to experiment and thus play actions rarely played in the past; and recency, alluded to in the discussion of belief-based models.

A third class of models, initially proposed by Camerer and Ho [32], is known as *experienced weighted attraction (EWA)*, and is a synthesis of the basic features of the belief-based and reinforcement-learning approaches. It encompasses a variety of formulations of either of them. A more elaborate version of it is called self-tuning EWA [33], because the weights evolve as play unfolds.

Other classes of models consider other aspects of adaptive behavior. For example, in symmetric games, it is quite plausible that people resort to imitating the play of others [34]. A different perspective is that of Stahl [35] who pursues the idea that people behave according to rules, switching between rules according to their relative performance.

Although different models approach adaptive dynamics from different angles, in many games they end up making very similar predictions. This observational equivalence in actions tells us that a deeper understanding of the issues might have to rely on observing and modeling other aspects of people's

decision process. A way of doing so involves tracking people's informational searches of elements of the game such as their own payoffs or their opponents' payoffs as well as the actions that their opponents play as the game unfolds, as in Knoepfle *et al.* [36]. Knoepfle *et al.* [36] study generates intriguing results because while the analysis of the information looked at by the subjects suggests that they engage in sophisticated learning (i.e., they take into account how their actions will influence the actions of their opponents in future periods), rather than adapting to the past as in standard belief-based or reinforcement-learning models or mixtures of both, the action data do not support this hypothesis. The intricacies of behavior highlighted in this study tell us that we will need to consider the different dimensions of the decision process to clarify the issues and produce a synthesis of the different approaches.

CONCLUSIONS

Tests of game theory's behavioral predictions using economics experiments have produced overwhelming and systematic empirical evidence that people play games differently from what the theory predicts. This article provides brief summaries of different modeling approaches that incorporate empirically-based concepts into the theory. Although a lot of progress has been made, the challenge for game theory remains the same: to put forward models of behavior that can explain equilibrium play in some situations and nonequilibrium in others, but that are not tailored to each and every game in a way that renders them ad hoc; instead they should be parsimonious, even if their parameters have to be appropriately fine-tuned across different strategic situations.

BEHAVIORAL OPERATIONS: APPLICATIONS IN SUPPLY CHAIN MANAGEMENT

KAREN DONOHUE
ENNO SIEMSEN
Carlson School of Management,
University of Minnesota,
Minneapolis, Minnesota

How do trust and fairness factor into supply chain relationships? Why do supply chain professionals often place orders that do not correspond to the recommendations made by normative models? When does a stock-out upset customers and what impact should this have on supply chain execution?

Such questions fall under the banner of “Behavioral Operations,” a relatively new term for the study of human behavior as it impacts the performance and management of operations. While our purpose in this article is to focus on one segment of this field, namely, applications relevant to supply chain management, we begin with some background on the field as a whole.

A previous review defines behavioral operations as any study of operations “that explicitly incorporates social and cognitive psychology theory” (see Ref. 1, p. 679). Others extend its scope to include “the effects of human behavior in process performance, influenced by cognitive biases, social preferences, and cultural norms” (see Ref. 2, p. 15). Humans engage with operations in many ways: as workers performing a production or service activity, as managers setting operational policies or incentive schemes, and as customers judging and experiencing operational outcomes. While theory in the past has focused on establishing normative solutions within these contexts, behavioral operations is more descriptive in nature by aiming to deepen our understanding of these human interactions and decision making processes. It also follows the prescriptive goal of providing guidance on how to improve operations in light of this behavior.

One stream of literature within behavioral operations focuses on uncovering settings where humans make operational decisions, and interact with operational processes, in ways that differ from normative theory (see Ref. 2 for a summary). Understanding the causes of this behavior, and how they influence operational performance, is a major research goal. The cause of these deviations may be traced to specific decision biases, cognitive limitations, bounded rationality, social preferences, motivational issues, or other behavioral factors. This research draws from empirical observations made in the field or through controlled laboratory experiments. Analytical models are also used to test the impact of new behavioral assumptions and extend normative theory. Behavioral theories developed at a micro level draw heavily from findings in psychology, cognitive science, and behavioral economics, as well as other business disciplines such as consumer behavior and behavioral finance.

Another stream of research within behavioral operations examines how operations-specific policies or institutions should be structured in light of human dynamics that may have been uncovered in prior micro level research. Questions related to the design of procurement auctions, collaborative planning rules, and matching mechanisms fall into this category. This research tends to be prescriptive in nature. Here recommendations are often developed and tested analytically, based on specific assumptions of how individuals behave under the rules of the policy or institution. The robustness of the policy (and the underlying assumptions) is then tested in a series of studies, using a combination of numerical analysis and controlled laboratory experiments. Less work has been done at this more “macro” level, which we view as a fertile area for future research in behavioral operations. Excellent examples from economics include behavioral studies of alternative market designs [3] and matching mechanisms [4].

In addition to the previously mentioned reviews [1,2], two other references are useful for gaining a basic introduction to the general area of behavioral operations. The first introduces the underlying bodies of knowledge from other behavioral fields (including behavioral economics, judgment and decision making, social psychology, group dynamics, and systems dynamics) that are most germane to behavioral operations [5]. The second reference, reviews research within behavioral operations involving controlled experiments, and introduces a framework to organize this work based on the type of behavioral assumptions being investigated [6].

We emphasize that behavioral research is a substantive and not a methodological choice. Behavioral research is research that explores decisions that deviate from a normative, rational benchmark. It happens that experiments are a methodology that often fits research questions in behavioral research. Such experiments have two essential benefits [7]: they serve as a rigorous empirical pretest of theory prior to collecting field data, and they serve as an empirical feedback mechanism to further our theoretical developments. Unlike field data, experimental data is comparatively cheap. From an epistemological perspective, we can rarely adjust our theory based on refuted theoretical predictions from field data, since it is often impossible or prohibitively expensive to collect a new field data set to retest our theoretical adjustments. Experimental data, however, can be easily collected, and thus better serves as an efficient feedback mechanism in theory development. As Smith writes, “the fact that one can always run a new experiment means that it is never tautological to modify the model in ways suggested by the results of the last experiment” (see Ref. 7, p. 274).

Supply chain management is a particularly active area of application for experimental work. Of 52 publications identified as experimental research falling within the behavioral operations field in the 20 years spanning 1986–2006, more than a third can be categorized as supply chain related (see Ref. 6 for details).

While the line between the disciplines of supply chain management and operations is

somewhat blurred, for the purposes of this article, we limit the scope of supply chain management to the topics outlined in the section titled “Supply Chain Management” in this encyclopedia. This includes topics within supply chain design, product design, inventory management and control, supplier management and contracts, and supply chain collaboration. We divide our coverage of behavioral research within supply chain management into two major areas based on the unit of analysis.

The first area, outlined in the section titled “Individual Decision Making in Supply Chains,” considers the behavior of *individual* decision makers within supply chains. These include tactic decisions related to demand forecasting and inventory planning, as well as more strategic decisions involving product design. This individual decision context is characterized by a lack of direct interaction with other decision makers. Note that this does not imply that interactions do not occur, but rather that they take a back seat when compared to the individual decision biases and errors in choice that are the main focus of study.

The second area, outlined in the section titled “Interactions in Supply Chains,” examines behavior that occurs as a part of supply chain *interactions*. These include interactions within an organization and across organization boundaries (e.g., vertical interaction between a supplier–buyer or horizontal interaction across retailers or manufacturers). The development of this interaction-based behavioral research follows closely from the evolution of behavioral economics, which began with a focus on individual behavior and later developed into a subfield focused on behavioral game theory.

The section titled “Conclusion” concludes the article with a description of resources for learning more about the concepts and methodologies used in this rapidly growing field.

INDIVIDUAL DECISION MAKING IN SUPPLY CHAINS

Many supply chain activities involve making repetitive decisions at an individual level.

For example, an inventory analyst may develop demand forecasts and make order quantity recommendations for hundreds of products each month. Other decisions, such as the choice of product to launch or what design features to include, are encountered less frequently but have significant implications on supply chain performance. This section gives some background on why the behavioral assumptions of rational choice may breakdown in these settings, focusing specifically on applications in forecasting, inventory management, and product design.

Some Background: Rational versus Behavioral Decisions

The field of supply chain management is rooted in the theory of industrial organization, and so it is not surprising that it initially inherited the rational choice paradigm from this subfield of microeconomics. Rational choice proposes rationality of outcomes more than processes [8], and encompasses four behavioral assumptions: (i) that behavior is mostly motivated by self-interested and stable monetary concerns, or by the utility derived from amassing wealth; (ii) that behavior is based on conscious, cognitive, and deliberate decisions; (iii) that such decisions are based on all available information; and (iv) that these decisions optimize a given objective function. Any deviations in human behavior from assumptions (i) to (iv), for example, the study of alternative objective functions to pure monetary concerns, or the study of decisions based on heuristics rather than optimal behavior, can be seen as deviations from rational choice, and are therefore elements of a behavioral research framework.

The pursuit of such deviations of rationality became possible within economics with the seminal work of Kahneman and Tversky [9,10]. Prospect theory, which reintroduces a stronger process perspective to the analysis of decisions, essentially deviates from rational choice by, on the one hand, emphasizing the role of framing into decision making, and on the other by insisting that utility not necessarily derives from accumulating wealth, but from gaining and losing wealth. Ever since, many more such systematic deviations from rational choice have been reported,

like the anchor and insufficient adjustment heuristic, where people incorporate irrelevant information into their decisions [11], or the problem of representativeness, where people believe that the law of large numbers applies to small samples as well [12]. Interested readers are referred to the section titled “Psychological Basis of Decision Making under Uncertainty and Risk” in this encyclopedia, which examines the psychological basis of decision making under uncertainty and risk.

Applications to Forecasting

Forecasting, in specific time series analysis, is essential for the success of any planning process. Since most companies still rely extensively on human judgment when preparing forecasts [13], an understanding of how humans react to time series data is a behavioral kernel of successful supply chain management.

One stream of research that has analyzed human reactions to time series is the literature on judgmental forecasting (see Ref. 14 for a recent review). While research in this area has mostly focused on comparing the performance of humans in analyzing time series with the performance of computer algorithms, some of this research has been devoted to understanding the behavior of forecasters and analyzing their biases [15,16]. An anchor and “excessive” adjustment heuristic seems to fit the observed forecast data well [17]. The precise nature of human behavior when faced with time series, though, seems to depend on the actual time series being analyzed [18].

A related stream of research focuses on the detection of regime-shifts, that is, structural changes in a data generating process [19]. Subjects in such experiments observe a series of data, and need to decide at what time, within the series, the data generating process switches to a different distribution. Results show that sometimes people tend to overreact [20], that is, indicate a change where in fact no change has occurred, and other times underreact [21], that is, not indicate a change even though it occurred. In a recent study, these thoughts were integrated into a

system-neglect hypothesis, which supported the notion that people underreact when the observed signal is precise and the underlying series is unstable, whereas they overreact to a stable time series with a noisy signal [22].

For a more complete understanding of behavioral forecasting, it is necessary to combine these thoughts on the detection of regime change with judgmental time series analysis [23]. Single exponential smoothing adequately describes subject behavior in many time series. In unstable time series, subjects tend to mistake successive random level changes for a trend. Further, conforming with the system-neglect hypothesis, subjects in stable time series tend to overreact to their forecast error, whereas in unstable time series, they tend to underreact to it. For more information on forecasting techniques, see the section titled “Forecasting Techniques” in this encyclopedia. The article titled ***Product/Service Design Collaboration: Managing the Product Life Cycle*** also provides an overview of collaborative forecasting methods within a supply chain environment.

Applications to Inventory Planning

Much of the behavioral research on inventory planning has focused on the problem of ordering for uncertain demand, rather than on the problem of balancing fixed ordering cost with variable holding cost. Since behavioral research in economics has focused on the question of judgment under uncertainty, this focus is not surprising. In a seminal experimental study, researchers subjected graduate students to the task of finding order quantities when faced with random demand with a constant unit cost of ordering too much and ordering too little, a scenario commonly referred to as the *newsvendor problem* [24]. A central finding of this study, which has been replicated many times [25,26], is that participants in these experiments on average order too little when faced with high profit products (i.e., high underage costs), and too much if faced with low profit products (i.e., low underage costs), compared to the optimal solution. This bias appears robust to differences in framing in terms of gains and losses (i.e., the

predictions of prospect theory do not apply) [27]. While this effect decreases with subject experience and training [28], no technique has been found to completely overcome this decision bias.

Many explanations have been put forward to explain this behavioral phenomenon. Schweitzer and Cachon favor the explanations that participants have some utility of reducing *ex post* inventory error, and that they anchor their decisions upon mean demand, and insufficiently adjust toward the optimal order quantity [24]. Other experiments have shown that subjects use a multitude of different anchors if provided in the experiment [29]. Analytical research has shown that such behavior can also be explained by adding noise into the participant's decision, such that subjects tend only to stochastically favor an optimal solution, in the sense that such a solution has a higher likelihood of being chosen, without choice being deterministic in these regards [30]. This notion has also been supported with experimental evidence [31]. Other research measured these sources of error in terms of level and adjustment bias, and introduce the notion of observation bias that may occur when demand is censored (i.e., when the level of lost sales is not known) [32]. While most of this research focuses on understanding aggregate behavior across a population, the data suggests that behavior varies significantly at the individual level. This begs the question of whether there are individual characteristics or cognitive tendencies that one can use *a priori* to predict performance. Research suggests that an individual's level of cognitive reflection (measured by the Cognitive Reflection Test) is a strong predictor of newsvendor performance [33]. Interested readers are referred to the section titled “Inventory Management and Control” in this encyclopedia for more information on inventory management, including the article titled ***Newsvendor Models***, which focuses on the newsvendor problem.

Applications to Product Development

Decisions made in product development have crucial implications for supply chains, such

as determining which components will be produced by whom within the supply chain, what assembly process will be used, and how the supply chain should be configured [34]. One crucial component of modern product development is the use of cross-functional teams to speed up and better integrate the necessary information flow. As such, much research exists that analyzes the behavioral implications of such teams, such as the factors within these teams that create innovativeness [35], how working in such teams leads to job stress and less cohesion [36], and how collaboration among team members can be induced by the perceived procedural fairness of top management decisions [37].

In addition to this literature on product development teams, research has also analyzed the decisions of individuals involved in the product development process. While the field has an extensive normative literature on areas like optimal design and optimal testing, less research exists that explicitly complements this normative perspective with a behavioral point of view. With respect to the behavior of designers, an objective to establish ones reputation in an organization can lead to a preference for more complex and difficult designs than necessary [38]. Decisions of designers to rework parts of their design depend on the knowledge diversity that exists in the direct network around a designer [39]. Further, designers tend to be present-biased, causing them to postpone possibly crucial design tasks to a later time [40]. Finally, providing designers with explicit cost data focuses their decision making on cost at the possible detriment of other design objectives [41]. The section titled “Supply Chain Design” in this encyclopedia offers more information on product design, while the section titled “Product Design and Life Cycle Management” in this encyclopedia focuses on the interaction between product design and life cycle management.

Future Research

The previous examples highlight that current individual level behavioral research in supply chain management is focused on a small number of mostly stochastic decision problems like the newsvendor, whereas the

pantheon of decision contexts that exist in supply chain management is large, diverse, and often unexamined through a behavioral lens. The potential for more behavioral work in the area is therefore large.

Take aggregate production planning and strategic capacity management as an example: How do people deal psychologically with the pressure to adjust capacity to fluctuating market requirements? Will decision makers tend to overreact when faced with demand fluctuations? What is the impact of a crises and disruption on decision making in a supply chain? Will people correctly identify the benefits of pooling for supply chain design [42]? How do people value information in a supply chain? These are important supply chain questions for which little behavioral theory exists.

INTERACTIONS IN SUPPLY CHAINS

A common research question in supply chain management is how should interactions between supply chain partners be designed and managed. The rules of interaction take many forms, including formal supply contracts, data sharing schemes, and collaborative planning, forecasting, and replenishment programs. Many of these interactions contain a game theoretic dynamic where individuals attempt to maximize their own local objectives and, in the process, may undermine the performance of the supply chain as a whole. This section provides background on behavioral issues that may arise in such interactions and highlights possible applications to multiechelon inventory systems, buyer–supplier relations, and procurement markets.

Some Background: Fairness, Trust, and Game Theoretic Behavior

When two or more individuals interact, new psychological factors may arise in addition to the biases and errors in judgment found in individual decisions. Examples include other-regarding preferences (such as fairness), dependences (such as trust), and a lack of understanding of game theoretic dynamics.

The behavioral economics literature identifies many forms of fairness, including distributive fairness, distributional fairness, and peer-induced fairness [43]. The form most applicable to supply chain management is, perhaps, distributional fairness, which implies that the utility of a given supply chain member is impacted by their individual payoff as well as the payoff distribution of others. This concern for fairness is often captured through an equity aversion utility function [44]. Most studies of fairness focus on the fairness of outcomes, although some also consider fairness in terms of the intentions behind the outcomes [45] or the process involved [46]. Closely related to fairness is the concept of reciprocity, which is the act of rewarding or punishing others in response to their behavior.

Trust differs from fairness in that it implies a relationship of reliance. In developing a construct for trust previous scholars [47], define three dimensions: (i) ability: perception of the skills and competencies of the trustee; (ii) benevolence: the extent to which the trustee is believed to want to do good for the other party; and (iii) integrity: perception that the trustee is honest and fulfills its promises. The importance of each dimension varies by problem context. How trust is regulated also differs with the stage of the relationship [48]. For example, early in the relationship parties may exhibit “calculus-based” trust, regulated solely by the relative benefits of keeping a promise versus the penalties of cheating. After repeated interactions predictability is paramount, making trust more “knowledge-based.” Finally, in long-term strategic relationships trust is “identification-based,” implying that the parties have fully internalized each others desires and intentions. Interested readers are referred to the section titled “Collective Choice and Social Utility Theory” in this encyclopedia, which examines collective choice and social utility theory.

When applying game theoretic models to a problem context, one must make specific assumptions about how players will behave in order to identify whether an equilibrium (Nash or otherwise) exists for the game. In reality, humans who interact in game-like

settings usually have limited knowledge of how others will behave. Because of this, strategic decision makers need to make a prediction about others behavior and then devise a “best response” strategy based on their beliefs. This raises several interesting questions for laboratory and field research, including: What type of predictions do people make about others’ behavior? How robust is ones “best response” strategy to errors in these predictions? Is there any evidence that people learn and converge to equilibrium after repeated interactions? Behavioral economists continue to develop new tools to model strategic interactions in light of these behavioral anomalies [49]. The section titled “Behavioral Economics and Game Theory” in this encyclopedia provides more detail on how the assumptions and descriptive power of game theoretic models can break down, and ways to remedy these gaps.

Applications to Multiechelon Inventory Systems

Managing multiechelon inventory systems is a critical internal function for any global product-based company. Many of the biases that occur when making order quantity decisions (as highlighted in the section titled “Applications to Inventory Planning”) continue to apply as the number of decision makers increases. However, errors in processing feedback and lack of trust introduce additional psychological factors that can further degrade performance.

The majority of behavioral research on multiechelon inventory systems focuses on the bullwhip effect, a phenomenon first introduced by Forrester [50]. The effect refers to the tendency for orders to increase in variability as one travels up a supply chain, away from the final customer. A seminal paper in the area [51], reports the results of a human experiment based on the Beer Distribution Game. This game mimics the dynamics of a decentralized, four-stage, serial supply chain with order and fulfillment delays between each stage. In this experiment, each supply chain consists of four people, taking the role of retailer, wholesaler, distributor, and manufacturer, who make inventory ordering decisions. (Note that when utilizing

the Beer Distribution Game for classroom learning purposes, other protocols are often followed, including assigning more than one person to each stage). Demand is unknown but all other operational causes of the bullwhip effect are controlled for, implying that any evidence of the bullwhip effect can be attributed to behavioral causes. The author finds that the resulting bullwhip effect is significant and points to individuals' failure to account for orders that have been placed but not yet received (i.e., underweighting the supply line) as the behavioral cause.

Other researchers have used a similar laboratory setting to test the impact of different demand patterns [52] and different institutions for reducing bullwhip behavior, including increasing information transparency in the form of point of sale data [52,53] and inventory information [54], and increasing ability-based trust [55]. See Ref. 53 for a review of research using the Beer Game prior to 2002. More recently, laboratory experiments have been used to test conditions thought to trigger order smoothing (rather than the order amplification inherent in the bullwhip effect). These laboratory results [56], along with field-based evidence [57], suggest that retailers smooth orders in response to seasonal demand, particularly when there are nontrivial costs to changing orders. Article titled *Information Sharing in Supply Chains* in this encyclopedia provides further insights into the challenges and opportunities offered by sharing information in supply chains.

Applications to Buyer–Supplier Interactions

In the supply chain literature, buyer–supplier interactions are often modeled as a Stackelberg game. In these games, the supplier traditionally acts as leader, making price or other contract parameter decisions subject to the ordering or retail price setting behavior of the buyer. Understanding this basic two-party dynamic is a critical building block for understanding strategic interactions in more complex supply networks.

One behavioral question that arises in this context is how does the form and framing of the contract influence the decision outcome? For example, suppose the supplier

has a choice of using a wholesale price-only, buyback, or revenue sharing contract (see the section titled “Supply Chain Scheduling” in this encyclopedia for more details on these and other contract structures). Analytical research based on rational choice assumptions shows that the buyback and revenue sharing contracts are equivalent in outcomes and dominate the wholesale price-only contract in terms of the average channel profit and supplier profit. Recent analytical research [58] finds that when incorporating fairness considerations into the buyer's utility function, the efficiency of the wholesale price-only contract improves. However, the level of efficiency achieved is impacted, in part, by the supplier's knowledge of the buyer's fairness concerns. When the buyer's fairness concern is private information, Katok and Pavlov [59] prove analytically that the resulting wholesale price-only contract may be rejected by the buyer with some positive probability. This result is also confirmed empirically through a series of experiments. Other authors [60] compare the performance of buyback and revenue sharing contracts in the laboratory and find that differences in the timing of payment across the two contracts matters to suppliers, at least initially. As a result, suppliers induce lower order quantities under a buyback contract—a behavior consistent with loss aversion. In a different channel setting, where demand is fixed and the buyer is charged with setting the market price, Ho and Zhang [61] find that framing a fixed fee as a quantity discount versus a two-part tariff leads to different pricing behavior, again consistent with loss aversion and prospect theory. In a similar setting, Lim and Ho [62] show that the buyer is more sensitive to the number of price blocks provided than normative theory suggests. In particular, theory suggests that two price breaks are optimal while laboratory studies show that offering additional price breaks further increases the supplier's profit.

Another important question is how will the parties share information? For example, if the retailer has better demand forecast information or the manufacturer has better production cost information, will this

information be passed to the other party without distortion? Game theory provides important insights, in the form of signaling and screening games, for developing contracts that induce truth telling. However, recent laboratory results suggest that such contracts may not always be necessary since human decision makers appear more trustworthy than rational choice theory would suggest. A series of laboratory experiments [63] find that even when a buyer has no financial obligation tied to his forecast (i.e., when the forecast is “cheap talk”), the level of forecast distortion is remarkably low. Other researchers [64] examine a screening game in a laboratory setting, where the buyer’s type (in terms of high, medium, or low demand) is not known to the supplier. They find that the recommended menu of contracts, which takes the form of a series of quantity discounts, can actually reduce the supplier’s profit relative to a wholesale price-only contract in some cases. It appears that the additional complexity introduced by a truth-inducing contract makes it difficult for the supplier to price accurately and for the buyer to interpret these prices.

Recently, Loch and Wu [65] found that informal interactions between parties, something as simple as having a supplier and buyer meet and shake hands, can lead to outcomes with higher distributional fairness. In a multiechelon context, Wu and Katok [66] also find that allowing a brief meeting with supply chain partners leads to decisions with higher payoffs for the supply chain as a whole.

Applications to Procurement Markets

There is a rich literature in behavioral economics on negotiations [67] and the performance of alternative mechanism designs for markets such as auctions (see Refs 68 and 69 for reviews as well as the section titled “Game Theory: Extension and Development” in this encyclopedia). However, the requirements of procurement markets, which are most relevant to the supply chain discipline, uncover some new and interesting complications.

For example, many companies now use reverse auctions to purchase some fraction of their direct and indirect materials. In setting up a reverse auction, a buyer must decide

on the type of scoring function to use to evaluate bids and provide feedback to the suppliers. Devising a scoring function that supports the preferences of the buyer can be difficult when the buyer values nonprice attributes that are multidimensional or difficult to communicate, such as service or quality levels. Even when a proposed function is theoretically proven to be efficient, there is no guarantee that it will perform well in practice, since suppliers in the field may have difficulty interpreting its more complex form. Controlled laboratory experiments with human subjects provide an important proof of concept test for such multiattribute reverse auctions. Laboratory studies provide insight into how factors, such as number of suppliers, or correlation between price and quality, impact the efficiency of reverse auctions under different scoring rules [70–72].

Procurement markets also differ from other exchanges in the types of costs incurred by the bidders/suppliers. For example, suppliers often face fixed costs that are generally independent of the quantity won, but avoidable when the quantity won is zero. This is typical when there is a fixed cost involved in setting up a production line or hiring employees to support new demand needs. Such a cost structure is more difficult to handle within an auction because it implies a different demand threshold level (to cover fixed costs) for each possible bid price. A recent study [73] sheds light on how enriching the bidding language (through multipart bids) and enriching market feedback (through quantity-dependent pricing) impacts bidding behavior in a laboratory environment.

Future Research

The previous examples are a small sample of the type of supply chain interactions that may benefit from a behavioral lens. The field is still at its infancy in understanding how other-regarding preferences such as fairness and social status impact supply chain interactions, especially within organizations where collaborative planning processes take place. The role of reciprocity within supply chains is also not well understood. What causes a supply chain member to punish or reward other

members? What form does such reciprocity take?

Our understanding of trust within supply chain is also incomplete, with most studies so far focusing on “cheap talk” settings. More laboratory and field-based research is needed to understand when monitoring mechanisms (such as truth-inducing contracts or scorecards) are really required to ensure trustworthy behavior in a supply chain. It is also unclear how the stage of the supply chain relationship (captured through repeated interactions and reputation building) impact trust. Studies so far have focused mostly on “calculus-based” trust, typical of early stages.

Finally, we hope to see more strides in the future to implement natural experiments in the field, and to improve supply chain practice by designing better institutional mechanisms, and validating these using experiments. In this way, a number of research methodologies can be applied to provide a more complete picture of the behavioral implications of supply chain interactions.

CONCLUSION

Given the prominence that the behavioral approach to decision making has achieved within other business disciplines such as finance, accounting, and marketing, it is not surprising that research in supply chain management has shifted toward a more behavioral approach as well. Within this development, it is important to emphasize that behavioral research in supply chain management is not limited to the narrow psychological perspective of individual judgment and decision biases. If behavioral research is to capture all deviations from the traditional rational choice paradigm it must be broad and include, for example, the analysis of social interactions and cultural norms inherent in supply chain interactions. Our outline of supply chain applications highlights behavioral issues that arise at both the level of an individual decision maker and within the interaction of two or more supply chain members. We hope that

these examples stimulate more researchers to join in the pursuit of viewing supply chain decisions through a behavioral lens.

The following resources are helpful for learning more about the methodologies underlying behavioral operations. In addition to the review articles mentioned earlier [1,2,5,6], Friedman *et al.* [74] offer an overview of experimental economics, Kagel and Roth [75] give background on designing and running human experiments, and Ho *et al.* [76] provide insight into behavioral modeling and its application to business contexts such as marketing. Finally, Boudreau *et al.* [77] outlines opportunities for research on the interface between operations and human resources management.

BENDERS DECOMPOSITION

ZEKI CANER TAŞKIN

Department of Industrial Engineering,
Boğaziçi University, Bebek, Istanbul,
Turkey

An important concern regarding building and solving optimization problems is that the amount of memory and the computational effort needed to solve such problems grow significantly with the number of variables and constraints. The traditional approach, which involves making all decisions simultaneously by solving a monolithic optimization problem, quickly becomes intractable as the number of variables and constraints increases. Multistage optimization algorithms such as Benders decomposition [1], have been developed as an alternative solution methodology to alleviate this difficulty. Unlike the traditional approach, these algorithms divide the decision-making process into several stages. In Benders decomposition, a first-stage master problem is solved for a subset of variables, and the values of the remaining variables are determined by a second-stage subproblem *given* the values of the first-stage variables. If the subproblem determines that the proposed first-stage decisions are infeasible, then one or more constraints are generated and added to the master problem, which is then re-solved. In this manner, a series of small problems are solved instead of a single large problem, which can be justified by the increased computational resource requirements associated with solving larger problems.

The remainder of this article is organized as follows: We will first describe Benders decomposition formally in the section titled “Formal Derivation.” We will then discuss some extensions of Benders decomposition in the section titled “Extensions.” Finally, we will illustrate the decomposition approach on a problem encountered in Intensity Modulated Radiation Therapy (IMRT) treatment planning in the section titled “Illustrative Example,” and give a numerical example.

FORMAL DERIVATION

In this section, we describe Benders decomposition algorithm for linear programs. Consider the following problem:

$$\text{Minimize } c^T x + f^T y \quad (1a)$$

$$\text{subject to: } Ax + By = b \quad (1b)$$

$$x \geq 0, y \in Y \subseteq \mathbb{R}^q, \quad (1c)$$

where x and y are vectors of continuous variables having dimensions p and q , respectively, Y is a polyhedron, A, B are matrices, and b, c, f are vectors having appropriate dimensions. Suppose that y variables are “complicating variables” in the sense that the problem becomes significantly easier to solve if y variables are fixed, perhaps due to a special structure inherent in matrix A . Benders decomposition partitions Problem (1) into two problems: (i) a master problem that contains the y variables, and (ii) a subproblem that contains the x variables. We first note that Problem (1) can be written in terms of the y variables as follows:

$$\text{Minimize } f^T y + q(y) \quad (2a)$$

$$\text{subject to: } y \in Y, \quad (2b)$$

where $q(y)$ is defined to be the optimal objective function value of

$$\text{Minimize } c^T x \quad (3a)$$

$$\text{subject to: } Ax = b - By \quad (3b)$$

$$x \geq 0. \quad (3c)$$

Formulation (3) is a linear program for any given value of $y \in Y$. Note that if Problem (3) is unbounded for some $y \in Y$, then Problem (2) is also unbounded, which in turn implies unboundedness of the original problem (Eq. 1). Assuming boundedness of Problem (3), we can also calculate $q(y)$ by solving its dual. Let us associate dual variables α with constraints (3b). Then, the dual of

Problem 3 is as follows:

$$\text{Maximize } \alpha^T(b - By) \quad (4a)$$

$$\text{subject to: } A^T \alpha \leq c \quad (4b)$$

$$\alpha \text{ unrestricted.} \quad (4c)$$

A key observation is that feasible region of the dual formulation does not depend on the value of y , which only affects the objective function. Therefore, if the dual feasible region (Eqs 4b and 4c) is empty, then either the primal problem (Eq. 3) is unbounded for some $y \in Y$ [in which case the original problem (Eq. 1) is unbounded], or the primal feasible region (Eqs 3b and 3c) is also empty for all $y \in Y$ (in which case Eq. 1 is also infeasible). Assuming that the feasible region defined by Equations (4b) and (4c) is not empty, we can enumerate all extreme points $(\alpha_p^1, \dots, \alpha_p^I)$, and extreme rays $(\alpha_r^1, \dots, \alpha_r^J)$ of the feasible region, where I and J are the numbers of extreme points and extreme rays of Equations (4b) and (4c), respectively. Then, for a given $\hat{y}$ vector, the dual problem can be solved by checking (i) whether $(\alpha_r^j)^T(b - B\hat{y}) > 0$ for an extreme ray α_r^j , in which case the dual formulation is unbounded and the primal formulation is infeasible, and (ii) finding an extreme point α_p^i that maximizes the value of the objective function $(\alpha_p^i)^T(b - B\hat{y})$, in which case both primal and dual formulations have finite optimal solutions. On the basis of this idea, the dual problem (Eq. 4) can be reformulated as follows:

$$\text{Minimize } q \quad (5a)$$

$$\text{subject to: } (\alpha_r^j)^T(b - By) \leq 0 \quad \forall j = 1, \dots, J \quad (5b)$$

$$(\alpha_p^i)^T(b - By) \leq q \quad \forall i = 1, \dots, I \quad (5c)$$

$$q \text{ unrestricted.} \quad (5d)$$

Note that Problem (5) consists of a single variable q , and typically, a large number of constraints. Now we can replace $q(y)$ in Equation (2a) with Problem (5) and obtain a reformulation of the original problem in

terms of q and y variables.

$$\text{Minimize } f^T y + q \quad (6a)$$

$$\text{subject to: } (\alpha_r^j)^T(b - By) \leq 0 \quad \forall j = 1, \dots, J \quad (6b)$$

$$(\alpha_p^i)^T(b - By) \leq q \quad \forall i = 1, \dots, I \quad (6c)$$

$$y \in Y, q \text{ unrestricted.} \quad (6d)$$

Since there is typically an exponential number of extreme points and extreme rays of the dual formulation (Eq. 4), generating all constraints of type (6b and 6c) is not practical. Instead, Benders decomposition starts with a subset of these constraints, and solves a “relaxed master problem,” which yields a candidate optimal solution (y^*, q^*) . It then solves the dual subproblem (Eq. 4) to calculate $q(y^*)$. If the subproblem has an optimal solution having $q(y^*) = q^*$, then the algorithm stops. Otherwise, if the dual subproblem is unbounded, then a constraint of type (6b) is generated and added to the relaxed master problem, which is then re-solved. [Constraints of type (6b) are referred to as *Benders feasibility cuts* because they enforce necessary conditions for feasibility of the primal subproblem (Eq. 3).] Similarly, if the subproblem has an optimal solution having $q(y^*) > q^*$, then a constraint of type (6c) is added to the relaxed master problem, and the relaxed master problem is re-solved. (Constraints of type (6c) are called *Benders optimality cuts* because they are based on optimality conditions of the subproblem). Since I and J are finite, and new feasibility or optimality cuts are generated in each iteration, this method converges to an optimal solution in a finite number of iterations [1].

EXTENSIONS

Benders decomposition is closely related to other decomposition methods for linear programming (see *Relationship Among Benders, Dantzig-Wolfe, and Lagrangian Optimization*). Furthermore, Benders decomposition can be applied to a broader class of problems, some of which are

described in this section. We first observe that only linear constraints are added to the master problem throughout the iterations of Benders decomposition. Therefore, the master problem does not have to be a linear program, but can take the form of an integer (Ref. 1 and the section titled “Illustrative Example”), a nonlinear [2] or a constraint programming problem [3]. Also note that the subproblem is only used to obtain dual information in order to generate Benders cuts. Therefore, the subproblem does not have to be a linear program, but can also be a convex program since dual multipliers satisfying strong duality conditions can be calculated for such problems [4] for detailed information about convex optimization). The extension of Benders decomposition that allows for nonlinear convex programs to be used as subproblems is referred to as *generalized Benders decomposition* [5]. Similarly, “logic-based Benders decomposition” generalizes the use of linear programming duality in the subproblem to “inference duality,” which allows the use of logic-based methods for solving the subproblem and generating Benders cuts (see **Constraint Programming Links with Math Programming** for more information about constraint programming and its relationships with mathematical programming). In some applications subproblems can be solved efficiently by specialized algorithms instead of the explicit solution of linear programs [6,7]. If the subproblem is a linear feasibility problem (i.e., a linear programming problem having no objective function), cuts based on irreducible infeasible subsets of constraints can be generated using a technique known as *combinatorial Benders decomposition* [8].

It is often the case that decisions for several groups of second-stage variables can be made independently, given the first-stage decisions. In such cases, multiple subproblems can be defined and solved separately. For instance, in stochastic programming models, some action needs to be taken in a first stage, which is followed by the occurrence of a random event (typically modeled by a number of scenarios) that affects the outcome of the first-stage decision. A recourse decision can then be made

in a second stage after the uncertainty is resolved (see sections titled “Models” and “Two-Stage Stochastic Programming” of the encyclopedia for more information about two-stage stochastic programming models). In such problems, second-stage recourse problems can be solved independently given the first-stage decisions, and hence are amenable to parallel implementations [9].

ILLUSTRATIVE EXAMPLE

Problem Definition

In this section, we consider a matrix segmentation problem arising in IMRT treatment planning, which is described in detail in Ref. 10 (see also **Optimization Models for Cancer Treatment Planning** for an introduction to optimization models in cancer treatment). The problem input is a matrix of intensity values that are to be delivered to a patient from some given angle, under the condition that the IMRT device can only deliver radiation through rectangular apertures. An aperture is represented as a binary matrix whose ones appear consecutively in each row and column, and hence form a rectangular shape. A feasible segmentation is one in which the original desired intensity matrix is equal to the weighted sum of a number of feasible binary matrices, where the weight of each binary matrix is the amount of intensity to be delivered through the corresponding aperture. We seek a matrix segmentation that uses the smallest number of aperture matrices to segment the given intensity matrix. This goal corresponds to minimizing setup time in the IMRT context [10]. The example below shows an intensity matrix and a feasible segmentation using three rectangular apertures:

$$\begin{bmatrix} 2 & 7 & 0 \\ 2 & 10 & 3 \\ 0 & 8 & 3 \end{bmatrix} = 2 \times \begin{bmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix} \\ + 3 \times \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 1 & 1 \end{bmatrix} + 5 \times \begin{bmatrix} 0 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 0 \end{bmatrix}.$$

We will denote the intensity matrix to be delivered by an $m \times n$ matrix B , where the element at row i and column j , (i, j) requires $b_{ij} \in \mathbb{Z}^+$ units of intensity. Let R be the set of all $O(m^2 n^2)$ possible rectangular apertures (i.e., binary matrices of size $m \times n$ having contiguous rows and columns) that can be used in a segmentation of B . For each rectangle $r \in R$, we define a continuous variable x_r that represents the intensity assigned to rectangle r , and a binary variable y_r that equals 1 if rectangle r is used in decomposing B (i.e., if $x_r > 0$), and equals 0 otherwise. We say that element (i, j) is “covered” by rectangle r if the (i, j) element of r is 1. Let $C(r)$ be the set of matrix elements that is covered by rectangle r . We define $M_r = \min_{(i,j) \in C(r)} \{b_{ij}\}$ to be the minimum intensity requirement among the elements of B that are covered by rectangle r . Furthermore, we denote the set of rectangles that cover element (i, j) by $R(i, j)$. Given these definitions, we can formulate the problem as follows:

$$\text{Minimize } \sum_{r \in R} y_r \quad (7a)$$

$$\text{subject to: } \sum_{r \in R(i, j)} x_r = b_{ij} \quad \forall i = 1, \dots, m, \\ j = 1, \dots, n \quad (7b)$$

$$x_r \leq M_r y_r \quad \forall r \in R \quad (7c)$$

$$x_r \geq 0, y_r \in \{0, 1\} \quad \forall r \in R. \quad (7d)$$

The objective function (Eq. 7a) minimizes the number of rectangular apertures used in the segmentation. Constraints (7b) guarantee that each matrix element receives exactly the required dose. Constraints (7c) enforce the condition that x_r cannot be positive unless $y_r = 1$. Finally, Equation (7d) states bounds and logical restrictions on the variables. Note that the Objective (7a) guarantees that $y_r = 0$ when $x_r = 0$ in any optimal solution of Problem (7).

Decomposition Approach

Formulation (7) contains two variables and a constraint for each rectangle, resulting in a large-scale mixed-integer program for problem instances of clinically relevant sizes. Furthermore, the M_r terms in constraints (7c)

lead to a weak linear programming relaxation due to the “big-M” structure. These difficulties can be alleviated by employing a Benders decomposition approach. Our decomposition approach will first select a subset of the rectangles in a master problem, and then check whether the input matrix can be segmented using only the selected rectangles in a subproblem. Let us first reformulate the problem in terms of the y variables.

$$\text{Minimize } \sum_{r \in R} y_r \quad (8a)$$

$$\text{subject to: } y \text{ corresponds to a} \\ \text{feasible segmentation} \quad (8b)$$

$$y_r \in \{0, 1\} \quad \forall r \in R, \quad (8c)$$

where we will address the form of Equation (8b) next. Given a vector $\hat{y}$ that represents a selected subset of rectangles, we can check whether constraint (8b) is satisfied by solving the following subproblem:

$$\text{SP}(\hat{y}) : \text{Minimize } 0 \quad (9a)$$

$$\text{subject to: } \sum_{r \in R(i, j)} x_r = b_{ij} \quad \forall i = 1, \dots, m, \\ j = 1, \dots, n \quad (9b)$$

$$x_r \leq M_r \hat{y}_r \quad \forall r \in R \quad (9c)$$

$$x_r \geq 0 \quad \forall r \in R. \quad (9d)$$

If $\hat{y}$ corresponds to a feasible segmentation then $\text{SP}(\hat{y})$ is feasible, otherwise it is infeasible. Note that Formulation (8) is a pure integer programming problem (since it only contains the y variables), and $\text{SP}(\hat{y})$ is a linear programming problem (since it only contains the x -variables). Furthermore, constraints (9c) reduce to simple upper bounds on x -variables for a given $\hat{y}$, which avoids the “big-M” issue associated with constraints (7c). Given a $\hat{y}$ -vector, if $\text{SP}(\hat{y})$ has a feasible solution $\hat{x}$, then $(\hat{x}, \hat{y})$ constitutes a feasible solution of the original problem (Eq. 7). On the other hand, if $\text{SP}(\hat{y})$ does not yield a feasible solution, then we need to ensure that $\hat{y}$ is eliminated from the feasible region of Problem (8). Benders decomposition uses the theory of linear programming duality to achieve this goal.

Let us associate variables α_{ij} with Equation (9b), and β_r with Equation (9c). Then, the dual formulation of $\text{SP}(\hat{y})$ can be given as:

$$\begin{aligned} \text{DSP}(\hat{y}) : \text{Maximize } & \sum_{i=1}^m \sum_{j=1}^n b_{ij} \alpha_{ij} \\ & + \sum_{r \in R} M_r \hat{y}_r \beta_r \end{aligned} \quad (10a)$$

$$\text{subject to: } \sum_{(i,j) \in C(r)} \alpha_{ij} + \beta_r \leq 0 \quad \forall r \in R \quad (10b)$$

$$\begin{aligned} \alpha_{ij} \text{ unrestricted } & \quad \forall i = 1, \dots, m, \\ j = 1, \dots, n & \quad (10c) \end{aligned}$$

$$\beta_r \leq 0 \quad \forall r \in R. \quad (10d)$$

Our Benders decomposition strategy first relaxes constraints (8b) and solves Problem (8) to optimality, which yields $\hat{y}$. If $\text{SP}(\hat{y})$ has a feasible solution $\hat{x}$, then $(\hat{x}, \hat{y})$ corresponds to an optimal matrix segmentation. On the other hand, if $\text{SP}(\hat{y})$ is infeasible, then the dual formulation $\text{DSP}(\hat{y})$ is unbounded [since the all-zero solution is always a feasible solution of $\text{DSP}(\hat{y})$]. Let $(\hat{\alpha}, \hat{\beta})$ be an extreme ray of $\text{DSP}(\hat{y})$ such that $\sum_{i=1}^m \sum_{j=1}^n b_{ij} \hat{\alpha}_{ij} + \sum_{r \in R} M_r \hat{y}_r \hat{\beta}_r > 0$. Then, all y vectors that are feasible with respect to Equation (8b) must satisfy

$$\sum_{i=1}^m \sum_{j=1}^n b_{ij} \hat{\alpha}_{ij} + \sum_{r \in R} (M_r \hat{\beta}_r) y_r \leq 0. \quad (11)$$

We add Equation (11) to Problem (8), and resolve it in the next iteration to obtain a new candidate optimal solution.

Now let us consider a slight variation of the matrix segmentation problem, where the goal is to minimize a weighted combination of the number of matrices used in the segmentation (corresponding to setup time) and the sum of the matrix coefficients (corresponding to “beam-on-time”). In IMRT treatment planning context, this objective corresponds to minimizing the total treatment time [10]. In order to incorporate this change in our model, we simply replace the objective function (Eq. 7a) with

$$\text{Minimize } w \sum_{r \in R} y_r + \sum_{r \in R} x_r, \quad (12)$$

where w is a parameter that represents the average setup time per aperture relative to the time required to deliver a unit of intensity.

The Benders decomposition procedure, discussed above, needs to be adjusted accordingly. We first add a continuous variable t to Formulation (8), which “predicts” the minimum beam-on-time that can be obtained by the set of rectangles chosen. The updated formulation can be written as follows:

$$\text{Minimize } w \sum_{r \in R} y_r + t \quad (13a)$$

subject to: y corresponds to a

$$\text{feasible segmentation} \quad (13b)$$

$$t \geq \text{minimum beam-on-time}$$

$$\text{corresponding to } y \quad (13c)$$

$$t \geq 0, y_r \in \{0, 1\} \quad \forall r \in R. \quad (13d)$$

Given a vector $\hat{y}$, we can find the minimum beam-on-time for the corresponding segmentation, if one exists, by solving:

$$\text{SPTT}(\hat{y}) : \text{Minimize } \sum_{r \in R} x_r \quad (14a)$$

$$\text{subject to: } \sum_{r \in R(i,j)} x_r = b_{ij} \quad \forall i = 1, \dots, m,$$

$$j = 1, \dots, n \quad (14b)$$

$$x_r \leq M_r \hat{y}_r \quad \forall r \in R \quad (14c)$$

$$x_r \geq 0 \quad \forall r \in R. \quad (14d)$$

Let α_{ij} and β_r be dual multipliers associated with constraints (14b) and (14c), respectively. Then, the dual of $\text{SPTT}(\hat{y})$ is:

$$\begin{aligned} \text{DSPTT}(\hat{y}) : \text{Maximize } & \sum_{i=1}^m \sum_{j=1}^n b_{ij} \alpha_{ij} \\ & + \sum_{r \in R} M_r \hat{y}_r \beta_r \end{aligned} \quad (15a)$$

$$\text{subject to: } \sum_{(i,j) \in C(r)} \alpha_{ij} + \beta_r \leq 1 \quad \forall r \in R \quad (15b)$$

$$\begin{aligned} \alpha_{ij} \text{ unrestricted } & \quad \forall i = 1, \dots, m, \\ j = 1, \dots, n & \quad (15c) \end{aligned}$$

$$\beta_r \leq 0 \quad \forall r \in R. \quad (15d)$$

Note that $\text{SPTT}(\hat{y})$ is obtained by simply changing the objective function of $\text{SP}(\hat{y})$, and $\text{DSPTT}(\hat{y})$ is obtained by changing the right hand side of Equation (10b) in $\text{DSP}(\hat{y})$. If $\text{DSPTT}(\hat{y})$ is unbounded, then we add a Benders feasibility cut of type (11) as before, and re-solve Problem (13). Otherwise, let the value of t in Problem (13) be $\hat{t}$, and the optimal objective function value of $\text{DSPTT}(\hat{y})$ be t^* . If $\hat{t} = t^*$, then $(\hat{y}, \hat{t})$ is an optimal solution of Problem (13), which minimizes the total treatment time. However, if $\hat{t} > t^*$, then we need to add a constraint that satisfies the following properties: (i) the optimal value of $t = \hat{t}$ if $\hat{y}$ is generated by Problem (13) in a future iteration, and (ii) the optimal value of $t \leq \hat{t}$ for all y . Benders decomposition, once again, uses linear programming duality theory to generate such a constraint. Let $\hat{\alpha}_{ij}$ and $\hat{\beta}_r$ be optimal dual multipliers. It can be seen that the following constraint satisfies both requirements.

$$t \geq \sum_{i=1}^m \sum_{j=1}^n b_{ij} \hat{\alpha}_{ij} + \sum_{r \in R} (M_r \hat{\beta}_r) y_r. \quad (16)$$

Numerical Example

In this section, we give a simple numerical example illustrating the steps of Benders decomposition approach on our matrix segmentation problem. Consider the input matrix $B = \begin{bmatrix} 8 & 3 \\ 5 & 0 \end{bmatrix}$. The set of rectangular apertures that can be used to segment B is:

$$R = \left\{ \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix}, \begin{bmatrix} 1 & 0 \\ 1 & 0 \end{bmatrix}, \begin{bmatrix} 1 & 1 \\ 0 & 0 \end{bmatrix} \right\}$$

Let the average setup time per aperture relative to the time required to deliver a unit of intensity be $w = 7$. Defining an x_r and a y_r -variable for each rectangle $r = 1, \dots, 5$, the problem of minimizing total treatment time can be expressed as the following mixed-integer program:

$$\begin{aligned} \text{Minimize } & 7 \times (y_1 + y_2 + y_3 + y_4 + y_5) \\ & + x_1 + x_2 + x_3 + x_4 + x_5 \end{aligned} \quad (17a)$$

$$\text{subject to: } x_1 + x_4 + x_5 = 8 \quad (17b)$$

$$x_2 + x_5 = 3 \quad (17c)$$

$$x_3 + x_4 = 5 \quad (17d)$$

$$x_1 \leq 8y_1, x_2 \leq 3y_2, x_3 \leq 5y_3,$$

$$x_4 \leq 5y_4, x_5 \leq 3y_5 \quad (17e)$$

$$x_r \geq 0, y_r \in \{0, 1\} \quad \forall r = 1, \dots, 5. \quad (17f)$$

For a given $\hat{y}$ -vector, the primal subproblem $\text{SPTT}(\hat{y})$ can be given as

$\text{SPTT}(\hat{y})$:

$$\text{Minimize } x_1 + x_2 + x_3 + x_4 + x_5 \quad (18a)$$

$$\text{subject to: } x_1 + x_4 + x_5 = 8 \quad (18b)$$

$$x_2 + x_5 = 3 \quad (18c)$$

$$x_3 + x_4 = 5 \quad (18d)$$

$$x_1 \leq 8\hat{y}_1, x_2 \leq 3\hat{y}_2,$$

$$x_3 \leq 5\hat{y}_3, x_4 \leq 5\hat{y}_4,$$

$$x_5 \leq 3\hat{y}_5 \quad (18e)$$

$$x_r \geq 0 \quad \forall r = 1, \dots, 5. \quad (18f)$$

Associating dual variables α_{11} with Equation (18b), α_{12} with Equation (18c), α_{21} with Equation (18d), and $\beta_1, \dots, \beta_5$ with Equation (18e), we get the dual subproblem $\text{DSPTT}(\hat{y})$.

$\text{DSPTT}(\hat{y})$:

$$\text{Maximize } 8\alpha_{11} + 3\alpha_{12} + 5\alpha_{21}$$

$$+ 8\hat{y}_1\beta_1 + 3\hat{y}_2\beta_2 + 5\hat{y}_3\beta_3$$

$$+ 5\hat{y}_4\beta_4 + 3\hat{y}_5\beta_5 \quad (19a)$$

$$\text{subject to: } \alpha_{11} + \beta_1 \leq 1 \quad (19b)$$

$$\alpha_{12} + \beta_2 \leq 1 \quad (19c)$$

$$\alpha_{21} + \beta_3 \leq 1 \quad (19d)$$

$$\alpha_{11} + \alpha_{21} + \beta_4 \leq 1 \quad (19e)$$

$$\alpha_{11} + \alpha_{12} + \beta_5 \leq 1 \quad (19f)$$

$$\alpha_{11}, \alpha_{12}, \alpha_{21} \text{ unrestricted} \quad (19g)$$

$$\beta_r \leq 0 \quad \forall r = 1, \dots, 5. \quad (19h)$$

Iteration 1. We first relax all Benders cuts in the master problem, and solve

$$\begin{aligned} \text{Minimize } & 7 \times (y_1 + y_2 + y_3 + y_4 + y_5) \\ & + t \end{aligned} \quad (20a)$$

$$\begin{aligned} \text{subject to: } & t \geq 0, y_r \in \{0, 1\} \\ & \forall r = 1, \dots, 5. \end{aligned} \quad (20b)$$

The optimal solution of Problem (20) is $\hat{y} = [0, 0, 0, 0, 0], \hat{t} = 0$. In order to solve the subproblem corresponding to $\hat{y}$, we set the objective function (Eq. 19h) to Maximize $8\alpha_{11} + 3\alpha_{12} + 5\alpha_{21}$, and solve DSPTT($\hat{y}$). DSPTT($\hat{y}$) is unbounded having an extreme ray $\alpha_{11} = 2, \alpha_{12} = -1, \alpha_{21} = -1, \beta_1 = -2, \beta_2 = 0, \beta_3 = 0, \beta_4 = -1, \beta_5 = -1$, which yields the Benders feasibility cut $8 - 16y_1 - 5y_4 - 3y_5 \leq 0$.

Iteration 2. We add the generated Benders feasibility cut to our relaxed master problem, and solve

$$\begin{aligned} \text{Minimize } & 7 \times (y_1 + y_2 + y_3 + y_4 + y_5) \\ & + t \end{aligned} \quad (21a)$$

$$\begin{aligned} \text{subject to: } & 8 - 16y_1 - 5y_4 - 3y_5 \leq 0 \\ & (21b) \end{aligned}$$

$$\begin{aligned} & t \geq 0, y_r \in \{0, 1\} \\ & \forall r = 1, \dots, 5. \end{aligned} \quad (21c)$$

An optimal solution of Problem (21) is $\hat{y} = [1, 0, 0, 0, 0], \hat{t} = 0$. We set the objective function (Eq. 19a) to Maximize $8\alpha_{11} + 3\alpha_{12} + 5\alpha_{21} + 8\beta_1$, and solve DSPTT($\hat{y}$). DSPTT($\hat{y}$) is, again, unbounded. An extreme ray is $\alpha_{11} = 0, \alpha_{12} = 0, \alpha_{21} = 1, \beta_1 = 0, \beta_2 = 0, \beta_3 = -1, \beta_4 = -1, \beta_5 = 0$, which yields the following Benders feasibility cut: $5 - 5y_3 - 5y_4 \leq 0$.

Iteration 3. We update our relaxed master problem by adding the generated Benders feasibility cut:

$$\begin{aligned} \text{Minimize } & 7 \times (y_1 + y_2 + y_3 + y_4 + y_5) \\ & + t \end{aligned} \quad (22a)$$

$$\begin{aligned} \text{subject to: } & 8 - 16y_1 - 5y_4 - 3y_5 \leq 0 \\ & (22b) \end{aligned}$$

$$5 - 5y_3 - 5y_4 \leq 0 \quad (22c)$$

$$\begin{aligned} & t \geq 0, y_r \in \{0, 1\} \\ & \forall r = 1, \dots, 5. \end{aligned} \quad (22d)$$

An optimal solution of Problem (22) is $\hat{y} = [0, 0, 0, 1, 1], \hat{t} = 0$. We set the objective function (Eq. 19a) to Maximize $8\alpha_{11} + 3\alpha_{12} + 5\alpha_{21} + 5\beta_4 + 3\beta_5$, and solve DSPTT($\hat{y}$). This time DSPTT($\hat{y}$) has an optimal solution $\alpha_{11} = 1, \alpha_{12} = 1, \alpha_{21} = 1, \beta_1 = 0, \beta_2 = 0, \beta_3 = 0, \beta_4 = -1, \beta_5 = -1$, and the corresponding objective function value is $t^* = 8$. Since $t^* > \hat{t}$, we generate the following Benders optimality cut: $16 - 5y_4 - 3y_5 \leq t$.

Iteration 4. The updated relaxed Benders master problem is:

$$\begin{aligned} \text{Minimize } & 7 \times (y_1 + y_2 + y_3 + y_4 + y_5) \\ & + t \end{aligned} \quad (23a)$$

$$\begin{aligned} \text{subject to: } & 8 - 16y_1 - 5y_4 - 3y_5 \leq 0 \\ & (23b) \end{aligned}$$

$$5 - 5y_3 - 5y_4 \leq 0 \quad (23c)$$

$$16 - 5y_4 - 3y_5 \leq t \quad (23d)$$

$$\begin{aligned} & t \geq 0, y_r \in \{0, 1\} \\ & \forall r = 1, \dots, 5. \end{aligned} \quad (23e)$$

An optimal solution of Problem (23) is $\hat{y} = [0, 0, 0, 1, 1], \hat{t} = 8$. Note that $\hat{y}$ is equal to the solution generated in the previous iteration, and therefore $t^* = 8$. Since $t^* = \hat{t}$, optimality has been reached and we stop.

INTRODUCTION

Clustering is the grouping of objects (samples) that possess similar properties (features). The groups are called *clusters*. In other words, the problem is to “guess” some kind of optimal grouping without having any information about the labels of the objects. On the other hand, in classification a labeled set of samples is given, known as *training set*. The problem is to establish a decision rule in order to classify an unlabeled set of new samples, known as the *test set*.

Biclustering, also known as *coclustering*, differs from clustering and classification, but still shares the basic concepts of samples and features and can be supervised or unsupervised. Input for this problem can be given in an $n \times m$ data matrix A in which every line corresponds to one sample and every column corresponds to one feature. The problem is to rearrange the lines and the rows of this matrix in a way that samples with “similar” expression profile are grouped together, and features that are expressed in the same sample are grouped together as well. Then, the numeric value of the matrix a_{ij} corresponds to the amount of expression of the j^{th} feature in the i^{th} sample.

A very common way to visualize biclustering data is heatmapping. A heatmap is an $n \times m$ checkerboard, where every square corresponds to a different element of data in matrix A . Every square is color coded and corresponds to a numeric value, which

determines the sample’s feature expression. Figure 1 is an example of a heatmap.

An excellent example illustrating the idea of biclustering comes from computational biology and more specifically from microarray analysis. In this example, every line of the $n \times m$ data matrix A corresponds to a small part of DNA and every column corresponds to a sequence. The numeric values of the data matrix indicate if the column sequence exists in every sample. Then the problem is to see which features (short sequences) are associated with which samples and group them into biclusters. This skill is essential for genotyping.

The organization of this paper is as follows: In section titled “Mathematical Formulation of Biclustering,” we give a mathematical description of the biclustering problem, in section titled “Algorithmic Approaches,” we present the main algorithmic approaches for solving biclustering, and in the last section we illustrate some additional applications taken from the field of data mining and computational forecasting.

MATHEMATICAL FORMULATION OF BICLUSTERING

In this section, we present a mathematical formulation of the biclustering problem. Let A be an $n \times m$ data matrix. Each element a_{ij} corresponds to the numeric value of the j^{th} feature for the i^{th} sample.

Let $I \subseteq \{1, 2, \dots, n\}$ represent a subset of row indices and $J \subseteq \{1, 2, \dots, m\}$ be a subset of column indices. Then the submatrix A_{IJ} of A that contains the elements from the selected rows and columns is called a *biclus-ter*. A collection of biclusters $A_{I_s J_s}, s = 1, \dots, S$ is called *biclustering*. It is natural to demand that the data within a bicluster possess certain property or criterion such as uniformity, high or low value, and so on. A typical goal of biclustering is to find a maximum size bicluster or biclusters without violating this criterion. Thus, biclustering is formulated as an optimization problem and presently is a

Figure 1. (a) Heatmap for a matrix before applying biclustering. (b) The same matrix permuted in such a way that the bicluster structure is clear.

promising emerging field of study in the operations research community.

The above definition allows two biclusters to share a common feature or sample. In some application, nonoverlapping partitioning is required. Thus, a more strict definition of biclustering is often used [1].

Consider a clustering of m samples into r nonoverlapping clusters $S_1, S_2, S_3, \dots, S_r$ and a clustering of n features in r other nonoverlapping clusters $F_1, F_2, \dots, F_r$. A biclustering B can be defined as the collection of groupings of sample sets and feature sets $B = \{(S_1, F_1), (S_2, F_2), \dots, (S_r, F_r)\}$; each pair of clusters (S_i, F_i) , $i = 1, \dots, r$ is called a *bicluster* or *cocluster*.

ALGORITHMIC APPROACHES

This section briefly discusses some well-known algorithms. The approaches herein address different aspects of biclustering classification, such as definition of the bicluster, the notion of good versus best biclustering, probabilistic versus stochastic structure of the data set, and so on.

Many of the optimization problems for biclustering are NP-hard [2]. Thus, finding the best or “nearly optimal” biclustering classification for large real-world problems is a challenging task requiring expertise in combinatorial optimization. A detailed discussion on complexity in biclustering can be found in surveys [3–5]. Some of the algorithms presented here are heuristics for finding sub-optimal classification, while others aim at finding exact optimal biclustering.

Let us start by considering a bicluster to be a “uniform” submatrix. To quantify the degree of similarity within a bicluster, Hartigan [6] introduces variance as:

$$\text{Var}(S_k, F_k) = \sum_{i \in F_k} \sum_{j \in S_k} (a_{ij} - \mu_k)^2,$$

where

$$\mu_k = \frac{\sum_{i \in F_k} \sum_{j \in S_k} a_{ij}}{|F_k| |S_k|}$$

is the average value of a bicluster. Assuming that biclusters with lower variance are better than those with higher variance leads to

minimizing:

$$\begin{aligned}\text{Var}(S, F) &= \sum_{k=1}^r \text{Var}(S_k, F_k) \\ &= \sum_{k=1}^r \sum_{i \in F_k} \sum_{j \in S_k} (a_{ij} - \mu_k)^2,\end{aligned}$$

where r is a predefined number of biclusters. Hartigan also considers other objective functions representing specific patterns (i.e., variance within the column). Cheng and Church [7] propose to measure mean squared residue score

$$\sum_{i \in F_k} \sum_{j \in S_k} (a_{ij} - \mu_{ik}^r - \mu_{jk}^c + \mu_k)^2,$$

where $\mu_{ik}^r = \frac{1}{|S_k|} \sum_{j \in S_k} a_{ij}$ is the mean of i^{th} row of bicluster k and $\mu_{jk}^c = \frac{1}{|F_k|} \sum_{i \in F_k} a_{ij}$ is the corresponding mean for the j^{th} column. The objective would be to find the maximum size square bicluster having low $H_k < \delta$ or to minimize sum square residue for a fixed number of clusters. Since these problems are NP-hard, greedy, and local search type heuristics, their combinations are used to find a local solution of good quality. One of the widespread residue minimization algorithms is the approach of Yang *et al.* [8] known as *flexible overlapping clustering* (FLOC). It is generalized for the case when some data are missing and based on a simple polynomial heuristic aimed at finding the biclusters with low residue values.

Spectral biclustering algorithms are based on singular value decomposition (SVD) of data set matrix. A is represented as a sum of linear combination of rank-1 matrices:

$$A = \sum_{i=1}^k \sigma_i u_i v_i^T.$$

Kluger [9] suggested the algorithm based on the observation that checkerboard pattern in the data set can be detected by finding piecewise blocks in the pairs of vectors u_i and v_i corresponding to singular values σ_i of high magnitude.

There are methods that are not based directly on SVD, but use this concept for

solving related optimization problems. An example of this is the algorithm suggested by Dhillon in Ref. 10. If the data set is represented as a bipartite weighted graph, then the biclustering is associated with the cut of minimal weight. Finding such a cut is NP-hard. To find an approximated solution, the heuristic utilizes the SVD of a matrix of special structure. Biclustering can be done using conventional clustering algorithms such as k -means or self-organizing maps (SOM). Double conjugated clustering (DCC) [11] consequently clusters feature space and sample space and iteratively updates spaces based on preceding clustering. The sequence of successive clustering terminates when classifications stop changing.

To ensure reliability of resulting biclustering Busygin, Prokopyev, and Pardalos introduced a notion of consistency [1]. Assuming we have a biclustering classification, we can compute the matrix of centroid vectors containing mean values of the features for each sample class

$$c_{ik} = \frac{\sum_{j \in S_k} a_{ij}}{|S_k|}.$$

Feature i is classified into class $\hat{k}$, if its mean value is the highest in the class ($c_{i\hat{k}} > c_{ik}$ for all $k \neq \hat{k}$). Similarly, the centroid matrix can be computed for feature vectors

$$d_{jk} = \sum_{i \in F_k} \frac{a_{ij}}{|F_k|}.$$

Sample j is classified to class k if $d_{j\hat{k}} > d_{jk}$ for all $k \neq \hat{k}$. If the inequalities $c_{i\hat{k}} > c_{ik}$ and $d_{j\hat{k}} > d_{jk}$ are held simultaneously, then the biclustering classification is consistent. The data set is called *conditionally biclustering* if consistent biclustering exists with respect to a predefined partial classification. A supervised biclustering algorithm based on solving 0-1 fractional problems, is introduced in Ref. 1. This algorithm finds a maximum cardinality subset of features that make the data set conditionally biclustering admitting.

Biclustering data set A can be thought of as a joint probability distribution of rows and

columns $p(x = i, y = j) \propto a_{ij}$. Dhillon *et al.* [12] proposed a biclustering algorithm that finds a local minimum for the loss of mutual information. The algorithm is based on the assumption that keeping proper features and samples in the same class is beneficial from the view of one word point of information theory.

Biclustering via Gibbs sampling [13] allows for assigning certain probabilities of the bicluster to rows and columns. The probabilities are iteratively updated using the Bayesian framework. Eventually, the bicluster consists of rows and columns in which estimated probability values exceed a certain threshold.

Another probabilistic approach is the statistical algorithmic method for biclustering analysis (SAMBA) [14]. This algorithm uses statistical reasoning to formulate biclustering as a maximum bounded biclique problem.

Coupled two-way clustering is an analog of the hierarchical algorithm for convenient clusters [15]. Set of samples and features is clustered into two classes each resulting in four biclusters. This process is repeated until certain stopping criteria (i.e., some statistical characteristics) hold.

The plaid model method [16] assumes that an ideal biclustering has diagonal dominating checkboard pattern and the same

background color outside the clusters. On the basis of this assumption, biclustering can be reduced to an optimization problem with objective function reaching the minimum on the above-mentioned pattern.

The surveys [3–5] contain comprehensive introduction to the state of art for biclustering algorithms.

APPLICATIONS

In the introductory part, we described the intuition behind the biclustering problem by showing a computational biology application of the problem. A lot of research works deals with data sets obtained from microarray data [7,11,13,15,17–21]. Other than microarray analysis, biclustering has been used for analyzing drug activity data [22] and nutritional data [16]. Biclustering is also used in text mining. In these instances, every line of the data matrix A corresponds to a dictionary word and every column to a specific document. Then the numerical value a_{ij} is the number of times that word i appears in document j [10,12,23]. Another interesting application of biclustering is in collaborative searching. In this case, biclustering attempts to identify users with similar preferences and make suggestions that fit the user's taste. Example for services that use collaborative

Microarray analysis	7,11,13,17 15,18–21	Gene	Specimen	Amount of gene expression
Drug activity	22	Chemical compounds	Chemical compound descriptor	Value of the chemical descriptor
Text mining (bag of words)	10,12,23	Word	Document	Number of times that i^{th} word appears in j^{th} document
Collaborative filtering	8,24–26	Users	Preferred movies	Rating of the i^{th} user for the j^{th} movie
Dimensionality reduction (databases)	27	Database queries	sources	Association of i^{th} query with i^{th} source
e-Politics	6	A citizen	Topics	Opinion of i^{th} citizen on j^{th} topic

The third, fourth, and fifth columns indicate the physical interpretation of every matrix row, column, and element numerical value for the specific application.

search are movie rental websites and on-line bookstores. An overview of the existing applications of biclustering can be found in Table 1.

CONCLUSION

Biclustering is a problem with uses in many emerging fields of science and engineering. In this article, we gave an overview of the major engineering/science applications, where biclustering is useful, and the most important algorithms for addressing this problem. Since microarray data analysis and text mining are developing rapidly, more theoreticians and practitioners will demonstrate an interest in biclustering. Further theoretical justification of the existing methods and a more thorough analysis of the algorithm (with respect to the quality of the solution) is definitely needed. As pointed out by Busygin *et al.* [3] in the conclusion of his review paper, “future development of biclustering should involve more theoretical studies of biclustering methodology and formalization of its quality criteria.”

BILEVEL NETWORK INTERDICTION MODELS: FORMULATIONS AND SOLUTIONS

R. KEVIN WOOD
Department of Operations Research,
Naval Postgraduate School,
Monterey, California

INTRODUCTION

A dictionary definition of *interdict*, in the military sense, is

to destroy, cut or damage by ground or aerial firepower (enemy lines of reinforcement, supply, or communication) in order to stop or hamper enemy movement and to destroy or limit enemy effectiveness [1].

This definition is unnecessarily restrictive—for instance, it should also include ship-based firepower—but the essence is reasonable: interdiction connotes preemptive attacks that limit an enemy's subsequent ability to wage war, or carry out other nefarious activities. The mathematical study of interdiction has focused primarily on *network interdiction*, in which an enemy's activities are modeled using the constructs of network optimization (e.g., maximum flows, multi-commodity flows, and shortest paths), and in which attacks target the network's components to disrupt the network's functionality. Depending on the type of network, targeted components can include bridges, road segments or interchanges, communications links or switches, and so on. This article focuses on the *bilevel network interdiction problem* (BNI), but the reader should note that much of the presentation extends to interdiction of more general systems.

Examples of what we now call network interdiction date from antiquity. Herodotus [[2] 9.49–50] describes how the Persian cavalry (in 479 BC) cut Greek supply lines and routes to water sources in a battle near the

Greek city of Plataea; Livy [3, 22.8] reports that (in 218 BC) the Roman Senate ordered bridges near Rome to be destroyed to slow the advance of Hannibal and his troops; Polybius [4, 9.7] gives a different chronology for the latter incident, but the interpretation as “network interdiction” remains. Two millennia later, the American Civil War is replete with examples of both Confederate and Union forces attacking roads, bridges, rail lines, and telegraph lines to hamper the enemy's resupply, movement, and communications [5, Chapter 4]. In World War II, German submarines interdicted, that is, sank, hundreds of Allied petroleum tankers that were traveling the sea lanes of the Atlantic Ocean and elsewhere [6, Appendix 17].

Allied bombing attacks during World War II on German-controlled oil refineries and synthetic-fuel plants exemplify a more general type of *system interdiction* or “economic warfare.” The German military was crippled by the lack of fuel and lubricants caused by the “Oil Plan,” as the attack strategy was called. Interestingly, an acrimonious debate was waged between the proponents of the Oil Plan (system interdiction) and proponents of the “Rail Plan” (network interdiction). The Rail Plan sought to destroy rail lines and other transportation assets in Europe to restrict the movement of the German troops and equipment that would counter the Allied D-Day offensive. Ultimately, parts of both plans were implemented [7, pp. 75–78, 174–175].

Network interdiction is an important part of modern warfare where attacks on key civilian and military infrastructure can help reduce an enemy's fighting effectiveness, while incurring only limited casualties to “friendly forces” [8,9]. When planning for such attacks, the “interdictor” is typically faced with this question: Given limited attack resources and possibly other restrictions (e.g., political considerations), which network components should be attacked to reduce the enemy's war-fighting capabilities most effectively? BNI addresses this question.

To provide background on the modern, mathematical study of network interdiction, we first make the following definitions and assumptions [10]:

1. The interdictor, called *attacker* hereafter, acts first by using limited interdiction resources to attack components of his enemy's network.
2. The enemy, or *defender*, observes the damage caused by the attack(s) and then operates the damaged network so as to maximize his own, well-defined objective-function value.
3. The attacker understands the defender's capabilities and goals, and chooses attacks that minimize the defender's maximum achievable objective-function value.

These standard assumptions lead to the formulation of BNI and more general system-interdiction models as a type of Stackelberg game: a two-person, zero-sum, sequential-play game with two stages [11,12].

Wollmer [13] studies the problem of finding the single “most vital link” in a capacitated flow network, in his case, the arc whose deletion minimizes the maximum s - t flow in the network. (The reader who is unfamiliar with the terminology of network flows, e.g., “ s - t flows,” may wish to consult a standard text such as Ahuja *et al.* [14].) Here, the attacker has enough interdiction resource to attack and destroy exactly one arc, and the defender's objective is to maximize s - t flow. Wollmer's work may represent the earliest mathematical investigation of an instance of BNI, although as early as 1955 researchers were investigating a simpler “single-level” network interdiction problem that seeks to eliminate all s - t flow efficiently [15].

Danskin [16] presents some of the fundamental theory of “max–min models,” which may be viewed as a generalization of BNI to system interdiction. (His “min” and “max” are reversed compared to our convention). Confusingly, “max–min” and similar terms are also used in the context of the more common two-person, zero-sum, simultaneous-play games [17, pp. 143–165]. For example, von Neumann [18] proves the famous “minimax theorem” for such games.

Mathematical studies of BNI began in earnest during the Vietnam War, with models applied to disrupt the flow of enemy troops and materiel [19,20]. Fulkerson and Harding [21] and Golden [22] investigate the problem of maximizing the length of the shortest path in a network—to slow enemy reinforcements, say—using models in which the length of each network arc can be increased linearly, within limits, based on the amount of interdiction resource applied to it. (This is a “max–min” variant of BNI.) These models are solved as parametric linear programs (LPs). The k -most-vital-arcs problem [23,24] is similar, but at most k arcs may be interdicted and interdiction decisions are discrete. In particular, an arc is attacked and destroyed and its length becomes infinite, or it is left untouched and keeps its nominal length. Ball *et al.* [25] show that problem to be NP-complete. Israeli and Wood [26] extend the k -most-vital-arcs problem to general resource constraints: their study of the *shortest-path network interdiction problem* (or “maximizing the shortest path”), makes important theoretical and computational contributions to the solution of BNI, in general.

Ratliff *et al.* [27] extend Wollmer's [13] model to the problem of finding a set of n arcs in a capacitated network whose deletion minimizes the maximum s - t flow. While investigating problems of drug interdiction, Wood [28] generalizes that model to allow general interdiction resource constraints. (Phillips [29] considers a similar model, but allows some continuous interdiction effort; see also Steinrauf [30].) Wood shows that this *maximum-flow interdiction problem* is NP-complete, even when attacks are constrained only in cardinality. Thus, even the simpler model of Ratliff *et al.* appears to be difficult.

More general system-interdiction issues arise in the work of Grötschel *et al.* [31] and Medhi [32] who seek to evaluate the vulnerability of information networks to interdiction. Chern and Lin [33] study the interdiction of a system represented as a minimum-cost network-flow model.

Similar to the BNI studied by Wood [28], the network interdiction model of Washburn and Wood [34] aims at disrupting drug smuggling, and its efficient solution

involves maximum flows. But this is a two-person, zero-sum, simultaneous-play (Cournot) game, and its purpose is quite different from BNI. Specifically, an interdicator controls one or more “inspectors” who must be placed strategically on the arcs of a transportation network to maximize the probability of detecting a drug smuggler moving surreptitiously through that network. (If the smuggler traverses arc k when an inspector is present, the smuggler is detected with known probability p_k ; otherwise he goes undetected.) In a simultaneous-play model, neither player can observe the other’s actions before acting himself and, consequently, solutions define probabilistic (“mixed”) strategies for both players. In this case, the interdicator’s strategy defines a probability distribution over the inspectors’ locations, and the smuggler’s strategy defines a probability distribution over paths through the network. In contrast, a solution to BNI prescribes deterministic (“pure”) strategies for both players.

Deterministic strategies do not imply that BNI cannot incorporate uncertainty and probability, however. Cormican *et al.* [35] develop stochastic-programming versions of the maximum-flow interdiction model to handle uncertain interdiction successes and uncertain arc capacities. Whiteman [36], studying interdiction problems faced by the US Strategic Command, addresses uncertainty through Monte Carlo simulations of maximum-flow interdiction models. Pan *et al.* [37] maximize the expected probability of detecting a smuggler trying to transport stolen nuclear materials out of a country: nominal probabilities of detection can be improved by installing a limited number of radiation detectors at border crossings. Maximizing probability of detection is related, through a logarithmic transformation in the objective function, to shortest-path interdiction, and in that sense the model is deterministic. The model is stochastic, however, in that a probability distribution describes the smuggler’s origin in the network [38].

Brown *et al.* [39,10] develop a taxonomy for bilevel system-interdiction and system-defense models, as well as for trilevel system-defense models. The bilevel and

trilevel models are two-stage and three-stage Stackelberg games, respectively. BNI is an instance of a two-stage “attacker–defender model”; the trilevel defense models are “defender–attacker–defender models.” In the latter case, a defender wishes to employ his limited defensive resources as efficiently as possible to “interdict the interdicator,” with effectiveness being evaluated by solving a bilevel interdiction model. Bilevel system-defense models can be constructed, also; these are “defender–attacker models”; they apply when the value of attacking a system component is a fixed or easily computed value; they can be solved using the techniques described in this article; but will not be discussed further. We note that Brown *et al.* [10,40] also discuss solution techniques for all these model types and describe a number of applications to infrastructure protection. Indeed, vulnerability analysis for infrastructure is an important new application area for BNI.

Most recently, bilevel interdiction and defense models have been developed for a number of interesting applications: theater ballistic missile defense [41], planning attacks on multicommodity flow networks [42], planning attacks on communications networks [43], delaying the nuclear-weapons project of a “rogue state” [44], and attacking and defending electric-power grids [45]. The theory of “global Benders decomposition” developed in the last paper promises to be a useful computational technique for BNI (and other optimization problems), and is discussed later in this article.

The goal of the rest of this article is to describe basic theoretical models and solution techniques for BNI. A lack of space prohibits further detailed discussion of applications. More information on advanced computational techniques can be found in Magnanti and Wong [46], Israeli and Wood [26], Salmerón *et al.* [45], and Smith *et al.* [47].

A BASIC, BILEVEL, INTERDICTION MODEL

In abstract form, BNI may be stated as the following *attacker–defender model*:

$$\begin{aligned}
[\text{AD0}] \quad & \min_{\mathbf{x} \in X} z_0(\mathbf{x}), \text{ where} \\
& z_0(\mathbf{x}) \equiv \max_{\mathbf{y} \in Y(\mathbf{x})} f(\mathbf{x}, \mathbf{y}), \quad (1)
\end{aligned}$$

and where (i) $\mathbf{x} \in X$ denotes a binary vector of attack decisions that is limited by resources and perhaps logical restrictions (e.g., targets k and k' both cannot be attacked); (ii) $\mathbf{y} \in Y(\mathbf{x})$ denotes the activities that the defender will carry on after the attack, typically restricted by effects of the attack $\mathbf{x}$; and (iii) the objective function $f(\mathbf{x}, \mathbf{y})$ measures the functionality of the defender's network after the attack. Thus, the attacker seeks to minimize the functionality of the network which the defender is assumed to maximize. Of course, by switching the min and the max, we can model an attacker who seeks to maximize the cost of the defender's operations.

[AD0] is a special case of a Stackelberg game in which a leader (attacker) takes some action, and a follower (defender) observes that action and its effects, and then responds optimally given that information (12). [AD0] is a two-stage game and is finished after the follower responds; more general Stackelberg games may have many stages and/or players.

For the sake of concreteness and simplicity, further development of [AD0] assumes that

1. The defender's activities take place on network arcs, which are indexed by k , and there is a one-to-one correspondence with the attacker's potential targets.
2. The defender nominally optimizes network operation by solving the following LP which is feasible for any $\mathbf{u} \geq \mathbf{0}$

$$\max_{\mathbf{y}} \quad \mathbf{c}^T \mathbf{y} \quad (2)$$

$$\text{s.t.} \quad \mathbf{A} \mathbf{y} \leq \mathbf{b} \quad (3)$$

$$0 \leq \mathbf{y} \leq \mathbf{u}, \quad (4)$$

3. Restrictions on the attacker assume $\mathbf{x} = \mathbf{0}$ is feasible, and are represented by

$$X = \{\mathbf{x} \in \{0, 1\}^n \mid H\mathbf{x} \leq \mathbf{h}\}, \text{ and } (5)$$

4. $x_k = 1$ implies that activity k is attacked, its level forced to 0, that is, $y_k = \mathbf{0}$.

Then, defining $U = \text{diag}(\mathbf{u})$, [AD0] takes on the following specific form

$$[\text{ADLP1}] \quad z_1^* = \min_{\mathbf{x} \in X} z_1(\mathbf{x}), \text{ where} \quad (6)$$

$$z_1(\mathbf{x}) \equiv \max_{\mathbf{y}} \quad \mathbf{c}^T \mathbf{y} \quad (7)$$

$$\text{s.t.} \quad \mathbf{A} \mathbf{y} \leq \mathbf{b} \quad (8)$$

$$0 \leq \mathbf{y} \leq U(\mathbf{1} - \mathbf{x}). \quad (9)$$

The inner LP in [ADLP1] might represent a simple maximum-flow problem [27,28], the optimal deployment of the defenders' armed forces [48], or the production and distribution of oil or natural gas in a belligerent country [49]. [ADLP1] extends easily to attacks on nodes, attacks on groups of arcs and/or nodes, attacks that reduce capacity only partially, and so on, but such extensions are straightforward and not considered here.

A Stackelberg game with mixed-integer variables and having just two levels of decision making is called a *bilevel mixed-integer program* (BLMIP) [50]. However, the leader's and follower's objective functions in a BLMIP are not usually diametrically opposed as they are in [AD0]; for example, see Bard and Moore [51], Wen and Yang [52], and Hansen *et al.* [53]. In fact, most algorithms developed for BLMIPs assume a strong positive correlation between the leader's and follower's objective functions. Thus, the theory and algorithms for BLMIPs do not seem well-suited for handling [ADLP1], while the special-purpose methods described in this article have had demonstrated successes.

Standard LP theory tells us that $z_1(\mathbf{x})$ is a concave function in (continuous) $\mathbf{x}$. Thus, [ADLP1] is a difficult, nonconvex minimization problem. The problem can be "convexified," however, by moving $\mathbf{x}$ into the objective of the inner maximization.

Proposition 1 [54]. *Let $\bar{r}_k$ be an upper bound on the optimal dual variable for the*

constraint $y_k \leq u_k(1 - x_k)$ in [ADLP1] taken over all $\mathbf{x} \in X$. Let $\bar{\mathbf{r}} = (\bar{r}_1 \dots \bar{r}_n)^T$ and $\bar{R} = \text{diag}(\bar{\mathbf{r}})$, and define

$$[\text{ADLP2}] \quad z_2^* = \min_{\mathbf{x} \in X} z_2(\mathbf{x}), \text{ where} \quad (10)$$

$$z_2(\mathbf{x}) \equiv \max_{\mathbf{y}} (\mathbf{c}^T - \mathbf{x}^T \bar{R}) \mathbf{y} \quad (11)$$

$$\text{s.t. } A\mathbf{y} \leq \mathbf{b} \quad [\mathbf{q}] \quad (12)$$

$$0 \leq \mathbf{y} \leq \mathbf{u}. \quad [\mathbf{r}]. \quad (13)$$

(The vectors $\mathbf{q}$ and $\mathbf{r}$, used later, denote dual variables for their respective constraint sets when $\mathbf{x}$ is fixed.) Then, [ADLP1] and [ADLP2] are equivalent in the sense that $z_1^* = z_2^*$, and $\mathbf{x}^*$ solves [ADLP2] if and only if it also solves [ADLP1].

Note also that $z_2(\mathbf{x})$ is a convex function in continuous $\mathbf{x}$.

That [ADLP2] is equivalent to [ADLP1] is intuitively clear, at least when the $\bar{r}_k$ are strict upper bounds: $(\mathbf{x}^*, \mathbf{y}^*)$ solves [ADLP1] if and only if it also solves [ADLP2]. Nonstrict bounds can lead to cases where $(\mathbf{x}^*, \mathbf{y}^*)$ is optimal [ADLP2] but infeasible to [ADLP1]. In this case, however, there must exist some $\mathbf{y}^{**}$ such that $(\mathbf{x}^*, \mathbf{y}^{**})$ is optimal to [ADLP1].

To solve [ADLP2], (i) temporarily fix the variables $\mathbf{x}$ in [ADLP2] (i.e., treat $\mathbf{x}$ as data); (ii) take the dual of the resulting LP; and (iii) then release $\mathbf{x}$. The following, equivalent mixed-integer program (MIP) results:

$$[\text{ADMIP2}] \quad \min_{\mathbf{x} \in X, \mathbf{q}, \mathbf{r}} \mathbf{b}^T \mathbf{q} + \mathbf{u}^T \mathbf{r} \quad (14)$$

$$\text{s.t. } A^T \mathbf{q} + I\mathbf{r} + \bar{R}\mathbf{x} \geq \mathbf{c} \quad (15)$$

$$\mathbf{q} \geq \mathbf{0}, \mathbf{r} \geq \mathbf{0} \quad (16)$$

A standard LP-based branch-and-bound algorithm will solve [ADMIP2] if that model is not too large.

Good dual bounds $\bar{\mathbf{r}}$ are important for solving [ADMIP2] directly, but are not easy to come by except in a few instances. For instance, if the inner LP in [ADLP] corresponds to a maximum-flow model with integral capacity vector $\mathbf{u}$, then $\bar{r}_k = 1$ is valid

and tight because the value of an extra unit of arc capacity in a maximum-flow problem is 0 or 1 [35]. Theoretically, we could also use $\bar{r}_k = 100$ in this case, but the resulting LP relaxation of [ADMIP2] would be weak and solution times would suffer.

The decomposition solution method for [ADLP2] described next does not eliminate the need for good bounds on dual variables, but ancillary techniques can alleviate some of the difficulties caused by weak bounds, and decomposition has some key advantages over a branch-and-bound solution of [ADMIP2].

1. In the context of network interdiction, various studies [55,26], have demonstrated that decomposition typically solves [ADMIP2] much faster than does branch-and-bound,
2. As we shall see, decomposition can be extended to solve BNI even when the defender's optimization model is more general than an LP, and
3. Decomposition methods typically solve a sequence of "defender subproblems" in a familiar, user-friendly form, which obviates the complicated, unfamiliar dual constructs of [ADMIP2]. For instance, Salmerón *et al.* [45] evaluate the effects of an attack plan $\mathbf{x}$ on a large, regional electric-power grid using a standard electric-power model. In contrast, a MIP formulation for BNI in this case becomes unwieldy (and can only be solved for small, unrealistic test problems) [56].

BENDERS DECOMPOSITION

The decomposition algorithm described here may be viewed as solving [ADLP2] by applying Benders decomposition to [ADMIP2] [57]. The Benders methodology for solving a minimizing MIP first converts the MIP into a min-max problem by reversing the steps that we used to create [ADMIP2] from [ADLP2]: (i) temporarily fix the integer variables, (ii) take the dual of the resulting LP, and (iii) release the integer variables [58, pp. 135–143]. In the case of [ADMIP2], this

conversion returns us to the more natural starting point of [ADLP2].

An optimal solution in $\mathbf{y}$ to [ADLP1] occurs at an extreme point of the (bounded) feasible region of that problem's inner LP. Because of the essential equivalence of the problems, the same holds true for solutions in $\mathbf{y}$ to [ADLP2]. Let Y denote the full, finite set of extreme points for the latter problem. Then, [ADLP2] may be expressed as this *equivalent master problem*

$$z_2^*(Y) = \min_{\mathbf{x} \in X} z_2(\mathbf{x}, Y), \text{ where} \\ z_2(\mathbf{x}, Y) \equiv \max_{\hat{\mathbf{y}} \in Y} \left(\mathbf{c}^T - \mathbf{x}^T \bar{\mathbf{R}} \right) \hat{\mathbf{y}}. \quad (17)$$

That model has this formulation as a MIP

[ADMP2(Y)]

$$z_2^*(Y) = \min_{\mathbf{x}, z} z \quad (18)$$

$$\text{s.t. } z + \hat{\mathbf{y}}^T \bar{\mathbf{R}} \mathbf{x} \geq \mathbf{c}^T \hat{\mathbf{y}} \quad \forall \hat{\mathbf{y}} \in Y \quad (19)$$

$$\mathbf{x} \in X. \quad (20)$$

Benders decomposition dynamically generates constraints (19) called *Benders cuts*. It solves or approximately solves the original problem by finding $\hat{Y} \subset Y$, with $|\hat{Y}| \ll |Y|$ it is hoped, so that [ADMP2($\hat{Y}$)] is an adequate approximation of the equivalent master problem.

Algorithm A-1. Basic Benders decomposition algorithm to solve [ADLP2]

Input: An instance of [ADLP2] and allowable optimality gap $\epsilon \geq 0$.
Output: An ϵ -optimal interdiction plan for [ADLP2], and associated objective value;
Step 0: $\hat{Y} \leftarrow \emptyset$; $\underline{z} \leftarrow -\infty$; $\bar{z} \leftarrow \infty$; $\hat{\mathbf{x}} \leftarrow \mathbf{0}$; $\hat{\mathbf{x}}^* \leftarrow \mathbf{0}$; $gap \leftarrow \infty$;
Step 1: Fix $\mathbf{x} = \hat{\mathbf{x}}$ in [ADLP2] and solve for $\hat{\mathbf{y}}$ and objective value $\hat{z} \equiv z_2(\mathbf{x})$; $\hat{Y} \leftarrow \hat{Y} \cup \{\hat{\mathbf{y}}\}$;
If $\hat{z} < \bar{z}$ then $\bar{z} \leftarrow \hat{z}$ and $\hat{\mathbf{x}}^* \leftarrow \hat{\mathbf{x}}$;
If $\bar{z} - \underline{z} \leq \epsilon$ then go to Step 3;
Step 2: Solve [ADMP2($\hat{Y}$)] for $z_2^*(\hat{Y})$ and $\hat{\mathbf{x}}$; $\underline{z} \leftarrow z_2^*(\hat{Y})$;
If $\bar{z} - \underline{z} > \epsilon$ then go to Step 1;
Step 3: Print "Approximate solution is," $\hat{\mathbf{x}}^*$, "with objective value," $\bar{z}$;
Print "Provable optimality gap is", $\bar{z} - \underline{z}$;
Stop;

End of Algorithm A-1.

Algorithm A-1, or simply "A-1," is actually a special case of Benders decomposition that does not require "feasibility cuts" [59]. Such cuts are needed if the subproblems can become infeasible for certain $\mathbf{x} \in X$, which ours cannot by assumption. The correctness of the algorithm is easy to see: (i) The upper bound $\bar{z}$ is valid because it corresponds to some feasible solution of [ADLP2] for the minimizing attacker; (ii) the lower bound $\underline{z}$ is valid because it corresponds to a relaxation of the equivalent master problem [ADMP2(Y)]; (iii) if a solution $\hat{\mathbf{x}}$ ever repeats, it follows that $\bar{z} = \underline{z}$ and the algorithm must terminate; and (iv) the termination criterion is satisfied with $\underline{z} \neq \bar{z}$ or a solution repeats in a finite number of steps because X is a discrete, finite set.

The following section describes some enhancements to A-1 that may improve

solution speeds, and shows how global Benders decomposition can actually solve more general problems than [ADLP2].

IMPROVING AND GENERALIZING BENDERS DECOMPOSITION

Faster Solutions with Super-Valid Inequalities

The (*relaxed*) master problem [ADMP1($\hat{Y}$)] can be strengthened in some instances by adding *super-valid inequalities* (SVIs). Intuitively, this strengthening can help alleviate some of the difficulties caused by weak dual bounds $\bar{\mathbf{r}}$. SVIs are similar to valid inequalities of integer-programming theory [60, pp. 205–295] except that they may, and typically do, eliminate feasible solutions from the

master problem. We define SVIs with respect to general MIPs.

Definition. Let $\mathbf{x}$ and $\mathbf{y}$ denote the vectors of integer and continuous variables, respectively, in a MIP. The inequality $\mathbf{w}_1^T \mathbf{x} + \mathbf{w}_2^T \mathbf{y} \geq w_0$ is *super-valid* for this MIP if (i) adding that inequality to the MIP does not eliminate all optimal solutions, or (ii) an incumbent solution $(\hat{\mathbf{x}}, \hat{\mathbf{y}})$ is (already) optimal for the MIP.

With proper precautions, SVIs may be used within a branch-and-bound algorithm for [ADMIP2] as well as within Benders decomposition for solving [ADLP2]. Suppose, for instance, that we add a single SVI in the course of solving a MIP by either technique. If case (i) is true for that SVI, then an optimal solution will still be found via enumeration because (a) some optimal solution is still feasible, and (b) any lower bound obtained from a relaxation of the SVI-modified MIP is still a valid lower bound on z_2^* . Thus, standard fathoming tests within a branch-and-bound algorithm and the convergence tests in A-1 are valid. If case (ii) is true when we add the SVI, we simply want our algorithm to halt with a message that the incumbent $\hat{\mathbf{x}}^*$ is optimal, and this is easy to arrange. After adding the SVI

1. If the MIP is found to be infeasible, or $\bar{z} > z(\hat{\mathbf{x}}^*)$, we declare the incumbent optimal, which it is, or
2. If $\bar{z} - \underline{z} \leq \epsilon$ occurs, we declare the incumbent to be ϵ -optimal, which it is. (As often happens, our incumbent is optimal, but we only prove it to be ϵ -optimal.)

By induction, it follows that an enumeration algorithm incorporating a finite number of SVIs will also terminate correctly and finitely.

One type of SVI for our enhanced version of A-1 applied to [ADLP2] is easy to derive.

Proposition 2 [26]. Let $z + \hat{\mathbf{y}}^T \bar{\mathbf{R}} \mathbf{x} \geq \mathbf{c}^T \hat{\mathbf{y}}$ denote a Benders cut from Algorithm A-1 being used to solve [ADLP2].

$$I_k(\hat{\mathbf{y}}) = \begin{cases} 1 & \text{if } \hat{y}_k > 0 \\ 0 & \text{otherwise.} \end{cases} \quad (21)$$

Then, the following inequality is super-valid:

$$\mathbf{I}(\hat{\mathbf{y}})^T \mathbf{x} \geq 1. \quad (22)$$

Suppose that $\bar{\mathbf{R}}$ derives from strict dual bounds and that $\hat{\mathbf{y}}$ is the response to the feasible interdiction plan $\hat{\mathbf{x}}$. It follows that $\hat{\mathbf{y}}^T \bar{\mathbf{R}} \hat{\mathbf{x}} = \mathbf{I}(\hat{\mathbf{y}})^T \hat{\mathbf{x}} = 0$, and that $\hat{\mathbf{x}}$ is made infeasible by the SVI $\mathbf{I}(\hat{\mathbf{y}})^T \mathbf{x} \geq 1$. That is, the inequality $\mathbf{I}(\hat{\mathbf{y}})^T \mathbf{x} \geq 1$ is not valid in the standard sense. Note also that $\hat{\mathbf{x}}$ could be an optimal solution which is made infeasible by the inequality, but if we already have an optimal solution in hand, we have free reign to restrict the solution in any way we like.

A simple extension of Proposition 2 leads to

Corollary 1. For every Benders cut $z + \hat{\mathbf{y}}^T \bar{\mathbf{R}} \mathbf{x} \geq \mathbf{c}^T \hat{\mathbf{y}}$, the SVI of Proposition 2 can be tightened to $\mathbf{I}(\hat{\mathbf{y}})^T \mathbf{x} \geq 2$ if $\mathbf{c}^T \hat{\mathbf{y}} - \max_i \bar{r}_i \hat{y}_i > \bar{z}$, can be tightened to $\mathbf{I}(\hat{\mathbf{y}})^T \mathbf{x} \geq 3$ if $\mathbf{c}^T \hat{\mathbf{y}} - \max_{k \neq k'} \{\bar{r}_k \hat{y}_k + \bar{r}_{k'} \hat{y}_{k'}\} > \bar{z}$, and so on.

Of course, as $\bar{z}$ changes during the course of A-1, it may be possible to tighten previously generated SVIs.

Modifications of A-1 to incorporate SVIs are straightforward, and SVIs may improve solution times substantially. Israeli and Wood [26] demonstrate this and show how to (i) add heuristically generated SVIs to an instance of [ADMIP2] to improve branch-and-bound solution times, (ii) generalize SVIs to “ ϵ -SVIs” that guarantee not to eliminate all ϵ -optimal solutions, and (iii) solve [ADLP1] and [ADLP2] in a decomposition algorithm whose master problem constraints consist solely of SVIs. The “covering algorithm” alluded to in (iii) uses no dual bounds $\bar{\mathbf{r}}$ at all, and converts Benders decomposition into a purely combinatorial procedure.

Standard Computational Enhancements for Benders Decomposition

In addition to employing SVIs, Algorithm A-1 can benefit from more standard techniques

used to improve solution speeds for Benders decomposition [46]. Some of these techniques are discussed briefly below.

1. For fixed $\mathbf{x}$, [ADLP2] may have multiple extreme-point solutions $\mathbf{y}$ and a different Benders cut can be generated for each. Adding too many such cuts can slow down solutions of [ADMP2], but adding them judiciously can improve solution times greatly. Israeli and Wood [26] use this technique in the shortest-path interdiction problem, where they enumerate multiple shortest paths for a single attack plan $\mathbf{x}$ and generate cuts for each.
2. The master problem need not be solved to optimality if “sufficient progress” is made after each cut is added [61].
3. Cuts derived from interior-point subproblem solutions $\hat{\mathbf{y}}$ may prove better than those derived from extreme-point solutions. For instance, an arc k with a large flow $\hat{y}_k$ on it appears as an attractive candidate for interdiction in the solution of the maximum-flow interdiction problem. That is, it generates a cut with a large-magnitude entry in position k . But $\hat{y}_k$ may be large primarily because the solution is an extreme-point solution, not because it must be large to achieve a maximum s - t flow. So, A-1 may waste time exploring solutions with $x_k = 1$. In contrast, an interior-point solution “spreads flow around” the network, and $\hat{y}_k$ will tend to be large only if it needs to be in order to achieve a maximum s - t flow. Consequently, better guidance and better cuts may be derived from such solutions.
4. Some Benders cuts can be dominated (implied) by others, and the nondominated ones ought to be used for the sake of efficiency. Magnanti and Wong [46] provide guidance on this topic. The related work of Smith *et al.* [47] may also prove useful: that paper shows how a polynomial-sized reformulation of the master problem in an interdiction model can yield cuts that dominate an exponential number of cuts from the original formulation.

Global Benders Decomposition

Algorithm A-1 can be extended to solve instances of [AD0], in which the defender’s operational model is more complicated than an LP. For example, let “[ADIP2]” denote a model identical to [ADLP2] except that $\mathbf{y}$ is required to be integral. A-1 clearly solves this problem because we can replace “the finite set of extreme points Y ” used to define the equivalent master problem [ADMP2] with “the finite set of integer solutions” for [ADIP2]. Geoffrion [62] coins the phrase “generalized Benders decomposition” to describe extensions of Benders decomposition to nonlinear models analogous to [ADLP2] with convex objective functions $z_2(\mathbf{x})$; Salmerón *et al.* [45] therefore use the phrase “global Benders decomposition” to describe the solution of other models like [ADIP2], in which the issues of convexity may even be irrelevant.

In [ADIP2], $\bar{r}_k$ no longer corresponds to a bound on a dual variable. Rather, that datum must comprise an integral part of the original formulation. For instance, [ADIP2] might correspond to a max–min instance of BNI in which an attacker seeks to delay completion of a defender’s project, which is modeled through the constructs of a resource-constrained PERT network. (Davis [63] discusses such PERT networks, and Brown *et al.* [40,44] discuss interdicting them.) If $x_k = 1$, task k in the project is attacked and delayed by a fixed amount: that is what $-\bar{r}_k$ would represent in [ADIP2]; otherwise $x_k = 0$ and task k requires some nominal time to complete, corresponding to c_k in that model.

We can generalize further.

Proposition 3 [45]. *Suppose that BNI has the following form:*

$$\begin{aligned}
 \text{[AD3]} \quad & \min_{\mathbf{x} \in X} z_3(\mathbf{x}), \text{ where} \\
 & z_3(\mathbf{x}) \equiv \max_{\mathbf{y} \in Y} f(\mathbf{x}, \mathbf{y}), \quad (23)
 \end{aligned}$$

and where X is defined as in Equation (5), $\mathbf{y} \in Y$ can be discrete and/or continuous, and $f(\mathbf{x}, \mathbf{y})$ has a general form. Furthermore, suppose that penalty vectors $\mathbf{v}(\mathbf{x})$ can be defined so that

$$z_3(\mathbf{x}) \geq z_3(\hat{\mathbf{x}}) + \mathbf{v}^T(\hat{\mathbf{x}})(\mathbf{x} - \hat{\mathbf{x}}) \quad \forall \mathbf{x}, \hat{\mathbf{x}} \in X. \quad (24)$$

Then, the following master problem is equivalent to [AD3]:

$$\begin{aligned} & \min_{\mathbf{x} \in X, z} z \\ & \text{s.t. } z - \mathbf{v}(\hat{\mathbf{x}})^T \mathbf{x} \geq z_3(\hat{\mathbf{x}}) - \mathbf{v}^T(\hat{\mathbf{x}})\hat{\mathbf{x}} \quad \forall \hat{\mathbf{x}} \in X \end{aligned} \quad (25)$$

Given the existence of an equivalent master problem, [AD3] may be solved via a modified version of A-1. We may assume that the attacker has an efficient method for computing $z_3(\hat{\mathbf{x}})$, that is, for evaluating the effects of an attack plan $\hat{\mathbf{x}}$ through the solution of the defender's subproblem. For instance, to evaluate the effects of attack plan $\hat{\mathbf{x}}$ on an electric-power transmission grid, the attacker can solve a nonlinear "AC optimal power-flow model" or a standard, faster, LP approximation, a "DC optimal power-flow model" [64]. Thus, the difficult part here will be defining and computing appropriate penalty vectors $\mathbf{v}(\mathbf{x})$. That task will be problem-dependent, so we expand upon the power-grid example to illustrate.

An attacker wishes to maximize the short-term, unserved demand for power in a defender's transmission grid. Thus, [ADMP3] must be converted to a maximization problem, and the inequality in Equation (26) reversed. When $\hat{x}_k = 0$, $v_k(\hat{\mathbf{x}})$ should bound the amount of unserved demand that will accrue if the status of grid component k is changed from "unattacked and functional" to "attacked and nonfunctional." The power-handling capability of the component provides a simple bound which is usually valid. If $\hat{x}_k = 1$, $v_k(\hat{\mathbf{x}})$ must reflect how much unserved demand will be eliminated if component k 's status is changed in the opposite direction. Because of the existence of series components, $v_k(\hat{\mathbf{x}}) = 0$ is a reasonable, albeit crude, approximation. (Actually, unserved demand can increase after repairing a component, but this does not normally cause difficulties [45]).

The subproblem in this example is merely a LP, and an attack on component k does force its capacity to 0 as in [ADLP1]. A

complication arises, however, because the destruction of a component can also improve power flow by eliminating one or more "susceptance constraints" between power lines having common end points [64]. Thus, $z_0(\mathbf{x})$ is neither concave nor convex in this application. However, this function tends to be well-behaved in practice, and the corresponding penalty vector $\mathbf{v}(\mathbf{x})$ is easily computed. The definition of that vector may seem simplistic, but Salmerón *et al.* [45] use it within global Benders decomposition to solve interdiction models on full-scale, regional transmission grids. An added benefit of the global Benders approach is that it extends to the trilevel network-defense problem for a power grid.

CONCLUSIONS

This article has described mathematical techniques for modeling and solving a BNI. BNI is a two-person, zero-sum, two-stage, sequential-play (Stackelberg) game whose solution prescribes an optimal application of limited resources to attack components of an enemy's network, and thereby limit that network's usefulness to the enemy. When a LP suffices to model optimal network operation, we show that BNI can be converted to and solved as a MIP. But, we describe special decomposition techniques that typically solve these problems more efficiently and, importantly, can solve more general problems.

BILINEAR OPTIMIZATION

CHURLZU LIM
University of North Carolina at
Charlotte, Charlotte, North
Carolina

PROBLEM DESCRIPTION

Bilinear optimization (or *bilinear programming*) problem (BLP) is a specially structured quadratic programming problem for general quadratic programming, where all quadratic terms are bilinear with respect to two disjoint sets of variables. Let $x \in R^n$ and $y \in R^q$ denote these two sets of variables. Then, a commonly used form of BLP can be written as follows: (More general forms of BLP problems will be discussed later.)

BLP:

$$\text{Minimize } f(x,y) = c^T x + d^T y + x^T Q y \quad (1a)$$

$$\text{subject to } x \in X = \{x \in R^n : Ax \geq b, x \geq 0\} \quad (1b)$$

$$y \in Y = \{y \in R^q : Fy \geq g, y \geq 0\}, \quad (1c)$$

where $c \in R^n$, $d \in R^q$, $Q \in R^{n \times q}$, $A \in R^{m \times n}$, $b \in R^m$, $F \in R^{p \times q}$, and $g \in R^p$. We assume that all vectors are column vectors unless otherwise noted, and T denotes the transpose operator. Note that there are quadratic terms in the objective function. Furthermore, x and y appear exclusively in the respective sets of constraints in Equations (1b) and (1c). Therefore, if the quadratic term in the objective function is removed, the problem is simply two separable linear programming problems. Due to these quadratic terms, however, the objective function becomes nonconvex, and hence, the problem becomes significantly difficult to solve. In particular, BLP is known to be *strongly NP-hard* [1].

Konno [2] lists important application problems that can be formulated as BLP. Such applications include game-theoretic problems (e.g., constrained bimatrix game, sequential game under perfect information), Markovian decision process (e.g., multistage Markovian assignment problem, multistage production, and sales optimization), complementary planning (e.g., complementary flows in a network, orthogonal production scheduling), and reformulation of other mathematical programming problems (e.g., concave quadratic minimization, 0–1 integer program). Other application problems include an inverse optimal value problem [3], estimation of population in finite-source election queues [4], and multicommodity network interdiction [5], to name a few.

CHARACTERIZATION OF BLP

Without loss of generality, assume that X and Y are nonempty and bounded. (Note that the problem can be unbounded if one or both of X and Y are unbounded. We will discuss how to check the unboundedness of BLP for such cases later in this section.) Therefore, there exists an optimal solution having a finite objective function value. One important property of BLP is that there exists an extreme point optimal solution (x^*, y^*) where x^* and y^* are extreme points of X and Y , respectively [6–8]. To be more specific, suppose that $(\bar{x}, \bar{y})$ is a nonextreme point optimal solution of BLP. Then, fixing $\bar{y}$ and solving BLP, we can find an extreme point solution x^* such that $f(x^*, \bar{y}) = f(\bar{x}, \bar{y})$ since it is a bounded linear programming problem. In turn, fixing x^* and solving BLP will yield an extreme point solution y^* such that $f(x^*, y^*) = f(x^*, \bar{y})$ due to the same reason as before. In consequence, there exists an extreme point optimal solution (x^*, y^*) of BLP.

Next, BLP can be interpreted as a concave minimization problem of either variable x or variable y . To illustrate this interpretation, consider the following problem, where

decision on y is delayed.

$$\begin{aligned} \text{Minimize} \quad & f_x(x) = c^T x + \left[\min_{y \in Y} d^T y + x^T Q y \right] \\ & (2a) \end{aligned}$$

$$\text{subject to} \quad x \in X. \quad (2b)$$

Since Y is nonempty and bounded, the above problem can be written as follows:

$$\text{Minimize} \quad \min_{y \in Y_E} \{ (c + Qy)^T x + d^T y \} \quad (3a)$$

$$\text{subject to} \quad x \in X, \quad (3b)$$

where Y_E denotes the set of all extreme points of Y . Note that the objective function is the minimum of a finite number of affine functions, which is a (multidimensional) piecewise affine concave function [9]. (Symmetrically, BLP can be interpreted as a concave minimization problem in variable y .)

BLP can be also viewed as a min-max problem. Let $v \in R^p$ denote the dual variable of the inner linear program in the problem (2). Then, since Y is nonempty and bounded, we can equivalently write the inner minimization problem as follows:

$$\begin{aligned} \text{Minimize} \quad & c^T x + \left[\begin{array}{ll} \max & g^T v \\ \text{s.t.} & F^T v \leq d + Q^T x \\ & v \geq 0 \end{array} \right] \\ & (4a) \end{aligned}$$

$$\text{subject to} \quad x \in X. \quad (4b)$$

Symmetrically, we can write an equivalent min-max problem by delaying decisions on x and taking the dual linear program of the inner problem in x .

Among numerous solution methods proposed in literature during the last four decades, we can observe two main-stream approaches; one is to exploit *Tuy cuts* (also referred to as *concavity cuts*) [10], and the other is to implicitly enumerate extreme points.

SOLUTION APPROACHES VIA TUY CUT AND ITS VARIANTS

Tuy cut was originally introduced for solving concave minimization problems in which a

concave objective function is minimized over a bounded polyhedral set [10], and it has played an important role in various algorithms for solving BLP as well as concave minimization problems. For illustrating Tuy cuts, consider the problem (2). Then, a Tuy cut in the x -variable space is generated by constructing a simplex having $n + 1$ vertices, at which objective function values are greater than or equal to the best available objective value, called the *incumbent value*. Due to the concavity of the objective function, it is guaranteed that the objective function value at a point in the simplex does not exceed the incumbent value. To be more specific, this simplex can be constructed as follows:

Consider a nondegenerate extreme point, x_1 , at which the objective function value is the incumbent value of $\bar{f}_x$. Due to nondegeneracy, there are n adjacent extreme points, $x_2, x_3, \dots, x_{n+1}$, which can be reached after single pivot. Furthermore, $x_1, x_2, \dots, x_{n+1}$ are affinely independent (i.e., $(x_2 - x_1), (x_3 - x_1), \dots, (x_{n+1} - x_1)$ are linearly independent). Assume that $f_x(x_j) \geq \bar{f}_x$ for $j = 2, 3, \dots, n + 1$. That is, x_1 is a local minimum in reference to its adjacent extreme points. Let $\lambda_j = \max\{\lambda > 0 : f(x_1 + \lambda(x_j - x_1)) = \bar{f}_x\}$. Furthermore, let $x'_j = x_1 + \lambda_j(x_j - x_1)$, that is, x'_j is on the ray $x_1 + \lambda(x_j - x_1)$ and is the farthest point from x_1 among points having the objective function value as $\bar{f}_x$. When such points exist on all n rays, the simplex is constructed by $(n + 1)$ vertices, $x_1, x'_2, x'_3, \dots, x'_{n+1}$. Accordingly, the Tuy cut eliminates the (open) halfspace which is formed by the hyperplane passing through $x'_2, x'_3, \dots, x'_{n+1}$ and by the region containing x_1 (see Fig. 1(a) for an illustrative example of $n = 2$). Tuy [10] exploits these cuts in the context of his *cone partitioning algorithm*, in which the cone defined by x_1 and n rays is recursively partitioned into subcones by adding a ray passing through a feasible point located farthest from the extreme point with respect to the Tuy cut until all subcones are covered by their own Tuy cuts. (See Fig. 1(b) for illustration of cone partitioning.)

One of the earliest adoptions of Tuy cuts within the context of BLP is made by Konno [6,8] who employs Tuy cuts to find ε -optimal solutions. Gallo and Ülkücü [11] employed

Figure 1. Illustrative examples for Tuy cut generation and cone partitioning. (a) A Tuy cut is generated at an incumbent extreme point x_1 . Due to concavity, $f_x(x) \geq \bar{f}_x$ for each x in the simplex. (b) Cone partitioning is made by adding a ray connecting x_1 and the extreme point of X which is farthest from x_1 with respect to the Tuy cut [23].

Tuy's cone partitioning algorithm in a straightforward manner. In Serali and Shetty [12], this type of cut is further enhanced by generating deeper cuts exploiting negative edge extension. Furthermore, in order to ensure finite convergence, their algorithm additionally generates disjunctive face cuts. Their negative edge extension scheme can be further enhanced by tighter bounding schemes of Ding and Al-Khayyal [13].

IMPLICIT ENUMERATION

Another main stream of solution efforts in BLP is implicit enumeration of extreme points. One notable approach is to solve the min-max formulation (4) via branch-and-bound methods. Note that the feasible region of (x, v) in the min-max problem is $S_{xv} = \{(x, v) : Ax \geq b, F^T v - Q^T x \leq d, x \geq 0, v \geq 0\}$. Furthermore, it has an optimal solution that is an extreme point of S_{xv} [7].

Consider the following relaxation of the min-max problem where the inner "maximization" is removed from the min-max problem.

$$\text{Minimize } c^T x + g^T v \quad (5a)$$

$$\text{subject to } F^T v - Q^T x \leq d \quad (5b)$$

$$Ax \geq b \quad (5c)$$

$$x, v \geq 0. \quad (5d)$$

Note that the optimal objective function value of this linear program is a lower bound of the optimal objective function value of the min-max problem (4). Let $\hat{x}$ denote the solution of x -variable to the linear program. Furthermore, let $\hat{y}$ be the solution to the following inner maximization problem.

$$\text{Maximize } g^T v \quad (6a)$$

$$\text{subject to } F^T v \leq d + Q^T \hat{x} \quad (6b)$$

$$v \geq 0. \quad (6c)$$

Since $(\hat{x}, \hat{y}) \in S_{xv}$, $c^T \hat{x} + g^T \hat{y}$ is an upper bound of the optimal objective value of the min-max problem (4). Hence, when the values of Equations (5) and (6) coincide, $(\hat{x}, \hat{y})$ is a global optimum of the min-max problem. Branching is triggered by designating the basic variable(s) in $\hat{x}$ as nonbasic. Note that there can be up to $q + m$ branches (see Equations (5b) and (5c)).

This branch-and-bound concept is also employed by Hansen *et al.* [1] for solving

linear bilevel programming problems via dichotomous branching, which is based on the complementary slackness of the inner linear program. Audet *et al.* [14] (and Alarie *et al.* [15] subsequently) employed the similar branching and bounding ideas to both symmetric min–max formulations as well as symmetric min–min formulations (i.e., delaying x or y as in Equation (2)).

LOCAL SEARCH

As far as approximation algorithms are concerned, so-called *mountain climbing* and *augmented mountain climbing* methods of Konno [6,8] are perhaps the most commonly practiced in literature as a local search procedure. Note that, given $x \in X$ (or $y \in Y$), BLP is a linear program in y (or x). Let $LP_{y|x}$ and $LP_{x|y}$ denote these linear programs, respectively. Then, starting at an initial point $x^0 \in X$ (typically, a basic feasible solution of X), the mountain climbing method alternately solves $LP_{y|x^i}$ and $LP_{x|y^i}$, where y^i is the solution to $LP_{y|x^i}$ and x^{i+1} is the solution to $LP_{x|y^i}$. The augmented mountain climbing method additionally employs a local search from the final solution of the mountain climbing method to find a better adjacent pair of extreme points, where the mountain climbing is employed again. The entire procedure is repeated until there is no better adjacent pair of extreme points.

BILINEAR PROGRAMMING AND GAME THEORY

While BLP has been used in many applications, its broad applicability comes from two types of game-theoretic problems; bimatrix game with side constraints and sequential game under perfect information. Bimatrix game is a two-person nonzero-sum and noncooperative game [16], where two players (denoted by P1 and P2, respectively) maximize their own payoffs without collaboration between the players. Let $X_G = \{x \in R^n : Ax \leq b, e_n^T x = 1, x \geq 0\}$ and $Y_G = \{y \in R^q : Fy \leq g, e_q^T y = 1, y \geq 0\}$ denote the sets of feasible mixed strategies of two players, where e_k is a vector of k ones. That is,

$x \in X_G$ (or $y \in Y_G$) is a vector of probabilities of n (q) pure strategies, where x (y) has additional side constraints $Ax \leq b$ ($Fy \leq g$). Furthermore, let $Q^1 = [q_{ij}^1] \in R^{n \times q}$ and $Q^2 = [q_{ij}^2] \in R^{n \times q}$ denote respective payoff tables of P1 and P2. Hence, q_{ij}^1 (or q_{ij}^2) is the payoff given to P1 (or P2), when pure strategies of P1 and P2 are i and j , respectively.

Note that, given (x, y) , expected payoffs of P1 and P2 are $x^T Q^1 y$ and $x^T Q^2 y$, respectively. A Nash equilibrium of this bimatrix game is mixed strategies (x^*, y^*) such that

$$(x^*)^T Q^1 y^* = \max \{x^T Q^1 y^* : x \in X_G\} \quad (7a)$$

$$(x^*)^T Q^2 y^* = \max \{(x^*)^T Q^2 y : y \in Y_G\}. \quad (7b)$$

The maximization problems in Equation (7) are linear programs. Loosely speaking, the idea to formulate BLP formulation is to put both maximization problems into a single problem, where the sum of duality gaps is minimized. To be more specific, the Nash equilibrium can be attained from the solution (x^*, y^*) of the following BLP problem [2]:

$$\text{Minimize } b^T u + \mu + g^T v + v - x^T (Q^1 + Q^2) y \quad (8a)$$

$$\text{subject to } A^T u + e_n \mu - Q^1 y \geq 0 \quad (8b)$$

$$F^T v + e_q v - (Q^2)^T x \geq 0 \quad (8c)$$

$$x \in X_G, y \in Y_G \quad (8d)$$

$$u, v \geq 0. \quad (8e)$$

Observe that constraint (8d) check primal feasibilities of Equations (7a) and (7b), and constraints (8b) and (8c) together with Equation (8e) enforce dual feasibilities of those linear programs. Furthermore, the objective function represents the sum of respective duality gaps of Equations (7a) and (7b), which will become zero at an optimal solution (see Konno [2] for more rigorous derivation).

Next, a sequential game under perfect information is a zero-sum game played by two players; (i) *leader* P1 who makes a feasible move $x \in X = \{x \in R^n : Ax \leq b, x \geq 0\}$, and (ii) *follower* P2 who then makes a move after fully observing the leader's move and its

impact. Due to the sequential order of decision making, the move of P2 (denoted by $v \in R^p$) is subject to the move of P1. In particular, let $V(x) = \{v \in R^p : F^T v \leq d + Q^T x, v \geq 0\}$ be the feasible region of moves of P2 (i.e., the move of P1 alters the resource vector of P2 by $Q^T x$). Assume, for simplicity, that $V(x)$ is nonempty and bounded for each $x \in X$. Since this is a zero-sum game, the gain of P2 is equivalent to the loss of P1. This gain (loss) is determined by the pair of moves x and v , and assume that the gain of P2 is $c^T x + g^T v$. Hence, given $x \in X$, P2 solves

$$\text{Maximize } c^T x + g^T v \quad (9a)$$

$$\text{subject to } F^T v \leq d + Q^T x \quad (9b)$$

$$v \geq 0, \quad (9c)$$

where the optimal objective function value is the loss of P1. Since the leader wants to minimize this loss, P1 solves

$$\text{Minimize } \begin{bmatrix} \max & c^T x + g^T v \\ \text{s.t.} & F^T v \leq d + Q^T x \\ & v \geq 0 \end{bmatrix} \quad (10a)$$

$$\text{subject to } x \in X. \quad (10b)$$

This problem is exactly the same as that of min-max problem (4), which is equivalent to Equation (1). In consequence, the sequential game with perfect information can be formulated as BLP.

UNBOUNDED FEASIBLE REGIONS

Earlier, we assumed that both X and Y are nonempty and bounded so that extreme point optimality is assured. However, if one (or both) of X and Y is unbounded, BLP could have an unbounded optimal objective value. Audet *et al.* [14] present how one can check boundedness of BLP by solving bounded BLP(s). While assuming X and Y are still nonempty, we first assume that only one feasible region is unbounded. Without loss of generality, assume that Y is unbounded. Since X is bounded, BLP becomes unbounded if and only if the inner minimization in Equation (2) is unbounded. In turn, from the relationship between primal

and dual linear programs in conjunction with $Y \neq \emptyset$, the inner minimization problem in Equation (2) is unbounded if and only if the feasible region of its dual linear program is empty. Hence, the equivalent condition is $V(x) = \emptyset$ for some $x \in X$, where $V(x) = \{v \in R^p : F^T v \leq d + Q^T x, v \geq 0\}$. Given $x \in X$, consider the following homogeneous form of the inner minimization problem:

$$\text{Minimize } d^T y + x^T Q y \quad (11a)$$

$$\text{subject to } F y \geq 0 \quad (11b)$$

$$y \geq 0. \quad (11c)$$

This problem has a nonempty feasible region (i.e., $y = 0$ is feasible). Hence, this problem is unbounded if and only if its dual problem has no feasible solution, which in turn implies the unboundedness of BLP as discussed above. Adding a constraint $e_q^T y \leq 1$ to Equation (11), let $Y_0 = \{y \in R^q : F y \geq 0, e_q^T y \leq 1, y \geq 0\}$. Then, the above homogeneous problem is unbounded if and only if the following bounded problem has a negative optimal objective function value [17]:

$$\min_{y \in Y_0} d^T y + x^T Q y. \quad (12)$$

Therefore, BLP is unbounded if and only if the following bounded BLP problem has a negative optimal objective value

$$\min_{x \in X, y \in Y_0} d^T y + x^T Q y. \quad (13)$$

Symmetrically, when X is unbounded and Y is bounded, BLP is unbounded if and only if the following problem has a negative optimal objective value

$$\min_{x \in X_0, y \in Y} c^T x + x^T Q y, \quad (14)$$

where $X_0 = \{x \in R^n : A x \geq 0, e_n^T x \leq 1, x \geq 0\}$.

When both X and Y are unbounded, Audet *et al.* [14] show that BLP is unbounded if and only if at least one of the following three BLP problems with bounded feasible regions has

a negative optimal objective value:

$$\begin{aligned}
\text{(I)} \quad & \min_{x \in \text{conv}(X_E), y \in Y_0} d^T y + x^T Q y \\
\text{(II)} \quad & \min_{x \in X_0, y \in \text{conv}(Y_E)} d^T y + x^T Q y \\
\text{(III)} \quad & \min_{x \in X_0, y \in Y_0} x^T Q y,
\end{aligned}$$

where $\text{conv}(\cdot)$ denotes convex hull of the set. (Recall that X_E and Y_E are sets of extreme points.) The first two problems (I) and (II) are direct derivatives of Equations (13) and (14). Solving (I) and (II), we can verify whether the unboundedness of BLP occurs when one of x and y is finite. The third case (III) is for checking unboundedness of BLP under the circumstance where $f(x, y) \rightarrow -\infty$ only if $\|x\| \rightarrow \infty$ and $\|y\| \rightarrow \infty$. Note that (III) can be solved via any solution methods discussed earlier since X_0 and Y_0 are nonempty and bounded. Furthermore, one can solve (I) and (II) via solution methods that find a best extreme point solution (e.g., implicit enumeration of Falk and Audet *et al.* [7, 14]), after replacing $\text{conv}(X_E)$ and $\text{conv}(Y_E)$ by the original polyhedral sets X and Y , respectively.

GENERALIZED FORMULATION

When variables x and y appear in the same constraint, the problem becomes *jointly constrained bilinear programming problem* (JBLP), and can be written as follows [18]:

$$\text{JBLP: Minimize } c^T x + d^T y + x^T Q y \quad (15a)$$

$$\text{subject to } Ax + Fy \geq b \quad (15b)$$

$$x, y \geq 0, \quad (15c)$$

where F is now $F \in R^{m \times q}$. When variables are jointly constrained, the extreme point optimality does not hold any more [18]. Instead, an optimal solution can be found along the boundary of the feasible region. Al-Khayyal and Falk [18] consider a linearly transformed version of JBLP, where $n = q$, $Q = I_n$ (i.e., n -dimensional identity matrix), and x and y explicitly bounded by a hyperrectangle. They employ a branch-and-bound method, where branching is performed by

partitioning a bounding hyperrectangle into subhyperrectangles, and where lower and upper bounds are derived by the minimum of a piecewise-linear convex underestimating function and by the original objective function value at the point, respectively. This branch-and-bound scheme is further enhanced by Sherali and Alameddine [19], who consider the original form of JBLP and apply the *reformulation-linearization technique* (RLT) to generate lower-bounding linear programs. RLT is originally designed to produce tighter linear programming relaxations for mixed-integer programming problems [20]. In their implementation for solving JBLP, the problem is first reformulated to an equivalent form by generating quadratic valid constraints. Then, quadratic terms are linearized by defining new variables to yield a linear program, which is shown to provide a tighter lower bound.

The most generalized form of bilinear program (GBLP) in the literature allows bilinear terms to appear in the constraint set of JBLP as follows [21]:

$$\text{GBLP: Minimize } c^T x + d^T y + x^T Q y \quad (16a)$$

$$\text{subject to } a_i x + f_i y + x^T P_i y \geq b_i \quad (16b)$$

$$x, y \geq 0, \quad (16c)$$

where $a_i \in R^n$ and $f_i \in R^q$ denote rows of A and F , respectively, and $P_i \in R^{n \times q}$. Linderoth [22] extends the branch-and-bound method of Al-Khayyal and Falk [18] by partitioning the feasible region into Cartesian product of triangles and rectangles. The branch-and-bound in conjunction with RLT for solving JBLP [19] is also extended by Sherali and Tuncbilek [23] for polynomially constrained polynomial programming problems, which subsume GBLP.

BIOSURVEILLANCE: DETECTING, TRACKING, AND MITIGATING THE EFFECTS OF NATURAL DISEASE AND BIOTERRORISM

RONALD D. FRICKER, JR.
Operations Research Department,
Naval Postgraduate School,
Monterey, California

INTRODUCTION

Bioterrorism is not a new threat in the twenty-first century—at least a thousand years ago, the plague and other contagious diseases were used in warfare [1,2] but today the potential for catastrophic outcomes is greater than it has ever been. To address this threat, the medical and public health communities are putting various measures in place, including biosurveillance systems designed to proactively monitor populations for possible disease outbreaks. The goal is to improve the likelihood that a disease outbreak, whether man-made or natural, is detected as early as possible so that the medical and public health communities can respond as quickly as possible. An ideal biosurveillance system analyzes population health-related data in near-real time to identify subtle trends not visible to individual physicians and clinicians. As they sift through data, many of these systems use one or more statistical algorithms to look for anomalies to trigger detection, investigation, quantification, localization, and outbreak management.

What is Biosurveillance?

Homeland Security Presidential Directive 21 (HSPD-21) defines biosurveillance as “the process of active data-gathering with appropriate analysis and interpretation of biosphere data that might relate to disease activity and threats to human or animal health—whether infectious, toxic, metabolic,

or otherwise, and regardless of intentional or natural origin—in order to achieve early warning of health threats, early detection of health events, and overall situational awareness of disease activity” [3]. As shown in Fig. 1, “biosphere data” can be divided into information about human, animal, and agricultural populations, and biosurveillance thus consists of health surveillance on each of these populations.

One particular type of biosurveillance is *epidemiologic surveillance* which HSPD-21 defines as “the process of actively gathering and analyzing data related to human health and disease in a population in order to obtain early warning of human health events, rapid characterization of human disease events, and overall situational awareness of disease activity in the human population.” Thus, epidemiologic surveillance addresses that subset of biosurveillance as it applies to human populations.

As shown in Fig. 2, epidemiologic surveillance is but one element of public health surveillance. Public health surveillance encompasses the surveillance of adverse reactions to medical interventions (particularly drugs and vaccines) and how health services are used, as well as epidemiologic surveillance. *Syndromic surveillance* is a specific type of epidemiological surveillance that has been defined as “the ongoing, systematic collection, analysis, interpretation, and application of real-time (or near-real-time) indicators of diseases and outbreaks that allow for their detection before public health authorities would otherwise note them” [4]. Thus, syndromic surveillance is epidemiologic surveillance restricted to using leading indicators of disease. In particular, syndromic surveillance is based on the notion of a *syndrome* which is a set of nonspecific prediagnosis medical and other information that may indicate the release of a bioterrorism agent or natural disease outbreak. See, for example, syndrome definitions for diseases associated with critical bioterrorism-associated agents [5].

Figure 1. Biosurveillance consists of human, animal, and agricultural surveillance. Animal surveillance may consist of monitoring certain animal populations for unusual behavior or excessive mortality as a leading indicator of an outbreak as well as zoonotic surveillance which refers specifically to animal diseases that can pass to humans. Agricultural surveillance may include monitoring livestock and plant diseases important to the human food chain.

Figure 2. A taxonomy of public health showing that epidemiologic surveillance is but one part of a broader set of surveillance activities. Adapted from Rolka and O'Connor [6].

Syndromic surveillance differs from traditional epidemiologic surveillance in a number of important ways. For example, syndromic surveillance often uses nonspecific health and health-related data (e.g., daily number of individuals seeking health care in an emergency room with sore throats), whereas traditional notifiable disease reporting is based on confirmed cases (e.g., daily number of individuals with laboratory-confirmed diagnoses). In addition, while in conventional public health surveillance it is unusual to initiate active surveillance without a known or suspected outbreak, syndromic surveillance systems actively search for evidence of possible outbreaks well before there is any suspicion of an outbreak.

Biosurveillance Objectives

Syndromic surveillance has also been defined as "...surveillance using health-related data that precede diagnosis and signal a sufficient probability of a case or an outbreak to warrant further public health response" [7,8]. This definition focuses on a number of ideas important to biosurveillance.

- First, biosurveillance is health surveillance, not military, regulatory or intelligence surveillance. It may use a wide variety of types of data, from case diagnoses to health-related data such as counts derived from chief complaints.
- Second, the data and associated surveillance are generally intended to precede

diagnosis or case confirmation in order to give early warning of a possible outbreak. Clearly, once a definitive diagnosis of a bioagent has been made, the need for detection becomes moot though tracking the location and spread of a potential outbreak is still important whether an outbreak has been confirmed or not.

- Third, the process must provide a signal of “sufficient probability” to trigger “further public health response.” Often the goal is not to provide a definitive determination that an outbreak is occurring but rather to signal that an outbreak *may* be occurring. Such a signal indicates further information is warranted through more detailed investigation by public health officials.

The motivation for biosurveillance, and syndromic surveillance systems in particular, is that some bioagents have symptoms in their prodromal stages similar to naturally occurring diseases. For example, in the first week or two after exposure to smallpox, individuals tend to have symptoms similar to the

flu such as fever, malaise, aches, nausea, and vomiting [9].

Biosurveillance systems have two main objectives: to support public health *situational awareness* (SA) and to enhance outbreak *early event detection* (EED). The CDC [10] defines them as follows:

- **SA** is the ability to utilize detailed, real-time health data to confirm, refute, and provide an effective response to the existence of an outbreak. It also is used to monitor an outbreak’s magnitude, geography, rate of change, and life cycle.
- **EED** is the ability to detect, at the earliest possible time, events that may signal a public health emergency. EED comprises case and suspect case reporting along with statistical analysis of health-related data. Both, real-time streaming of data from clinical care facilities as well as batched data with a short time delay are used to support EED efforts.

As illustrated in Fig. 3, biosurveillance systems are supposed to improve the chances of the medical and public health communities catching a disease outbreak early. The

Figure 3. An illustration of how biosurveillance is intended to improve the probability of detecting a disease outbreak, whether man-made or natural. The vertical axis is in terms of probability specifically because early event detection is a stochastic phenomenon. That is, whether and when a biosurveillance system detects an outbreak is a function of both, the aspects of the specific situation and chance.

more biosurveillance improves the probability of detecting an outbreak, the more a biosurveillance system is likely to enhance SA and EED. The goal is "...deployment of surveillance systems that can rapidly detect and monitor the course of an outbreak and thus minimize associated morbidity and mortality" [11].

When assessing biosurveillance systems, speed of (true positive) detection is one of three dimensions critical for completely characterizing performance. The other two dimensions are the rate of false positives and the probability of successfully detecting an outbreak. In the biosurveillance literature, these dimensions are often generically referred to as timeliness, specificity, and sensitivity.

All three dimensions are necessary and they trade off. For example, for a given EED methodology, improving the speed of detecting an outbreak generally comes at the cost of increasing the rate of false positives. Similarly, increasing the probability of detection usually comes at the expense of the speed of detection. These trade-offs are similar to the Type I and Type II error trade-offs inherent in classical hypothesis testing, though the sequential decision-making aspect of biosurveillance adds an additional level of complexity.

See Fricker [12], particularly the rejoinder, for a more detailed discussion about evaluating biosurveillance system performance and about the appropriate metrics for quantifying biosurveillance system performance.

BIOSURVEILLANCE SYSTEMS

As HSPD-21 states, "A central element of biosurveillance must be an epidemiologic surveillance system to monitor human disease activity across populations. That system must be sufficiently enabled to identify specific disease incidence and prevalence in heterogeneous populations and environments and must possess sufficient flexibility to tailor analyses to new syndromes and emerging diseases."

The use of biosurveillance, particularly in the form of syndromic surveillance, is widespread. In 2003, it was estimated that

approximately 100 state and local health jurisdictions were conducting some form of syndromic surveillance [4]. In 2004, Bravata *et al.* [11] conducted a systematic review of the publicly available literature and various web sites from which they identified 115 surveillance systems, of which they found 29 that were designed specifically for detecting bioterrorism. In 2007–2008, Buehler *et al.* [13] sent surveys to public health officials in 59 state, territorial, and large local jurisdictions. Fifty-two officials responded (an 88% response rate) representing jurisdictions containing 94% of the US population. They found that 83% reported conducting syndromic surveillance for a median of three years and two-thirds said they are "highly" or "somewhat" likely to expand the use of syndromic surveillance in the next two years.

Components

As depicted in Fig. 4, a biosurveillance system has four main functions: data collection, data management, analysis, and reporting. As illustrated in the figure, raw data enters the system at the left and as it flows through the system it becomes actionable information at the right.

Expanding on Rolka [14], the ideal system contains the following components:

- the original data, to which access is gained only after appropriately addressing legal and regulatory requirements, as well as personal privacy and proprietary issues;
- computer hardware and information technology for (near) real-time assembly, recording, transfer, and preprocessing of data;
- subject matter experts, data management, and data knowledge experts, as well as software and techniques for processing incoming data into analytic databases, including processes and procedures for managing and maintaining these databases;
- statistical algorithms to analyze the data for possible outbreaks over space and time that are of sufficient sensitivity to provide signals within an

- actionable time frame while simultaneously limiting false positive signals to a tolerable level;
- public health experts with sufficient statistical expertise that can appropriately choose and apply the algorithms most relevant to their jurisdiction and appropriately interpret the signals when they occur;
- data display and query software, as well as the necessary underlying data, that facilitates rapid and easy investigation and adjudication of signals by public health experts, including the ability to “trace back” from signal to likely source;
- other data displays, combined with decision support and communication tools, to support SA during an outbreak and to facilitate effective and efficient public health response;
- report production processes and access to supporting supplementary information;

Mandl *et al.* [15], in *Implementing Syndromic Surveillance: A Practical Guide Informed by the Early Experience*, provide a detailed discussion of what is required and guidance about how to implement biosurveillance systems.

Examples

Below are brief descriptions of three biosurveillance systems chosen to illustrate large-scale systems currently in operation. The first two are true systems, in the sense that they are comprised of both, dedicated computer hardware and software. The third is more properly described as a set of software programs that can be freely downloaded and implemented by any public health organization.

- BioSense.** Developed and operated by the Centers for Disease Control and Prevention (CDC), BioSense is intended to be a United States-wide

biosurveillance system. Begun in 2003, BioSense initially used the outpatient data of the Department of Defense and Department of Veterans Affairs, along with medical laboratory test results from a nationwide commercial laboratory. In 2006, BioSense began incorporating data from civilian hospitals as well. The primary objective of BioSense is to “expedite event recognition and response coordination among federal, state, and local public health and health-care organizations” [16,17].

- **ESSENCE.** An acronym for electronic surveillance system for the early notification of community-based epidemics, ESSENCE was developed by the Department of Defense in 1999. ESSENCE IV now monitors for infectious disease outbreaks at more than 300 military treatment facilities worldwide on a daily basis, using data from patient visits to the facilities and pharmacy data. For the Washington DC area, ESSENCE II monitors military and civilian outpatient visit data as well as over-the-counter (OTC) pharmacy sales and school absenteeism [18–20]. Components of ESSENCE have been adapted and used by some public health departments.
- **EARS.** An acronym for early aberration reporting system, EARS was and continues to be developed by the CDC. EARS was originally designed for monitoring for bioterrorism during large-scale events that often have little or no baseline data (i.e., as a short-term “drop-in” surveillance method) [21]. For example, the EARS system was used in the aftermath of Hurricane Katrina to monitor communicable diseases in Louisiana [22], for syndromic surveillance at the 2001 Super Bowl and World Series, as well as at the Democratic National Convention in 2000 [23]. Though developed as a stand-alone, portable surveillance analytic method, EARS data management procedures and algorithms have been adapted for use in many syndromic surveillance systems.

State and local biosurveillance systems may use EARS, BioSense, and in some cases ESSENCE, while some localities have instituted their own systems. Other biosurveillance and health surveillance systems include the real-time outbreak and disease surveillance system [24], the national notifiable diseases surveillance system [25], and the national electronic telecommunications system for surveillance [26]. Descriptions of some of these state and local systems (as well as other information) can be found in volume 53 of the CDC’s *Morbidity and Mortality Weekly Report* and the annotated bibliography for syndromic surveillance [27].

Among the more recent and unique surveillance efforts is Google Flu which is designed to track “health seeking” behavior in the form of search engine queries for flu-related information. As with syndromic surveillance systems using OTC medicine sales, the idea is that sick people first attempt to self-treat before seeking medical attention and, often, the first step is a search engine query for information. Figure 5 is a graph published in the *New York Times* comparing Google Flu’s estimated flu incidence based on search queries for flu-related terms to the CDC sentinel physician data. The figure shows a clear correspondence between the two time series. Ginsberg *et al.* [28, p. 1012] say, “Because the relative frequency of certain queries is highly correlated with the percentage of physician visits in which a patient presents with influenza-like symptoms, we can accurately estimate the current level of weekly influenza activity in each region of the United States, with a reporting lag of about one day.”

Another unique surveillance effort is HealthMap, a “multistream real-time surveillance platform that continually aggregates reports on new and ongoing infectious disease outbreaks” [29]. HealthMap extracts information from web-accessible information sources such as discussion forums, mailing lists, government web sites, and news outlets. It then filters, categorizes, and integrates the information and, as shown in Fig. 6, plots the information on a map. The goal of HealthMap is to provide real-time information about emerging infectious

PERCENT OF HEALTH VISITS FOR FLU-LIKE SYMPTOMS *Mid Atlantic region*

Using Google to Monitor the Flu

Figure 6. Screen shot of HealthMap map from June 5, 2010 [30].

diseases and is intended for use by both, public health officials and the traveling public [30]. As Brownstein *et al.* [29, p. 1019] say, “Ultimately, the use of news media and other nontraditional sources of surveillance data can facilitate early outbreak detection, increase public awareness of disease outbreaks prior to their formal recognition, and provide an integrated and contextualized view of global health information.”

BIOSURVEILLANCE UTILITY AND EFFECTIVENESS

In spite of the widespread and potentially expanding use of biosurveillance, questions remain about its utility and effectiveness. There are several examples of papers that discuss various issues, challenges, and important research needs associated with

effective implementation and operation of biosurveillance systems [4,7,11–14,31–35].

In case studies of health departments in eight US states, Uscher-Pines *et al.* [32] found that fewer than half had written response protocols for responding to biosurveillance system alerts and the health departments reported conducting in-depth investigations on fewer than 15% of biosurveillance system alerts. Further, Uscher-Pines *et al.* [32] said, “Although many health departments noted that the original purpose of syndromic surveillance was early warning/detection, no health department reported using systems for this purpose. Examples of typical statements included the following: ‘I was a big supporter of syndromic surveillance for early warning early on, but now I am more realistic about the system’s limitations.’ ”

In the literature, Reingold [35] suggested that a compelling case for the implementation of biosurveillance systems has yet to be made. Cooper [36] said, “To date no bioterrorist attack has been detected in the United Kingdom, or elsewhere in the world using syndromic surveillance systems.” Stoto *et al.* [34] questioned whether biosurveillance systems can achieve an effective early detection capability. And Green [33] said, “Syndromic surveillance systems, based on statistical algorithms, will be of little value in early detection of bioterrorist outbreaks. Early on in the outbreak, there will be cases serious enough to alert physicians and be given definitive diagnoses.”

The research challenges span many disciplines and problems:

- legal and regulatory challenges in order to gain access to data;
- technological challenges related to designing and implementing computer hardware and software for collecting and assembling data;
- ethical and procedural issues inherent in managing and safeguarding data;
- analytical challenges of assessing the likelihood of outbreaks and of displaying data to enhance SA;
- managerial challenges of effectively assembling and operating the entire system.

These research challenges are not necessarily of equal importance nor are they listed in any type of priority order. Furthermore, little is known about how they should be prioritized in terms of their contributions to improving the utility and/or effectiveness of biosurveillance. However, it is clear that improvements are necessary in all of these disciplines to achieve biosurveillance systems that are maximally useful and effective.

Much of the continuing controversy surrounding biosurveillance stems from its initial focus on EED, a use that requires a number of unproven assumptions, including

adequate strength such that they are statistically detectable with satisfactory power;

- leading indicators occur sufficiently far in advance of clinical diagnoses so that, when found, they provide the public health community with enough advance notice to take action;
- statistical detection algorithms exist that produce signals reliable enough to warrant continued dedication of public health resources to investigate the signals.

Of course, a myopic focus only on EED in biosurveillance systems misses important benefits such systems can provide, particularly the potential to significantly advance and modernize the practice of public health surveillance. For example, whether or not biosurveillance systems prove effective at the early detection of bioterrorism, they are likely to have a significant and continuing role in the detection and tracking of seasonal and pandemic flu, as well as other naturally occurring disease outbreaks. This latter function is echoed in an Institute of Medicine report on Microbial Threats to Health by Smolinski *et al.* [37]: “[S]yndromic surveillance is likely to be increasingly helpful in the detection and monitoring of epidemics, as well as the evaluation of health-care utilization for infectious diseases.” In a similar vein, Uscher-Pines *et al.* [32] quote a public health official: “Health departments should not be at the mercy of alerts; they need to develop their own uses for syndromic surveillance.”

In terms of bioterrorism, Stoto [38] states that biosurveillance systems build links between public health and health-care providers—links that could prove to be critical for consequence management should a bioterrorism attack occur. Furthermore, Sosin [4] points out that biosurveillance systems can act as a safety net should existing methods of detection fail to detect an attack. As such, biosurveillance can provide additional lead time to public health authorities so they can take more effective public health actions. For example, a Dutch biologist conducting automated salmonella surveillance related that the surveillance

- leading indicators of outbreaks exist in prediagnosis health-related data of

system detected an outbreak whose occurrence was somehow missed by sentinel physicians [39]. And unusual indicators in a biosurveillance system (not necessarily a signal from an EED algorithm) may give public health organizations time to begin organizing and marshaling resources in advance of a confirmed case and/or provide critical information about how and where to apply resources.

QUANTITATIVE METHODS USED IN BIOSURVEILLANCE SYSTEMS

Biosurveillance systems use a variety of temporal and spatial methods for EED. As is discussed in more detail below, most of these have been adapted from other fields and applications. Buckeridge *et al.* [40] provides a useful classification of common surveillance scenarios and a mapping of some EED methods to those scenarios.

SA is an emerging concept in biosurveillance and, as such, specific methods for assessing and displaying relevant information have not yet been incorporated into the systems. Currently SA is limited to displaying the spatial distribution of data via geographic information system (GIS) software. See, for example, Li *et al.* [41].

Temporal Methods

Most syndromic surveillance systems apply variants of the standard univariate statistical process control (SPC) methods: Shewhart, cumulative sum (CUSUM), and/or exponentially weighted moving average (EWMA) charts. Woodall [42] provides a comprehensive overview of the application of control charts to health surveillance. Montgomery [43] is an introduction to these methods in an SPC setting and Fricker [44] is a primer on how to apply these and other statistical methods to biosurveillance, both for EED and SA. Fricker [45], Shmueli and Fienberg [46], and Shmueli and Burkom [31] also review these and other methods potentially applicable to EED in a biosurveillance setting.

The challenge in applying these methods is that syndromic surveillance generally violates classical SPC assumptions. In SPC it is often reasonable to assume that

- since one controls the manufacturing process, the in-control distribution is (or can reasonably be assumed to be) stationary;
- observations can be drawn from the process so they are independent (or nearly so);
- monitoring the process mean and standard deviation is usually sufficient;
- the asymptotic distributions of the statistics being monitored are known and thus can be used to design appropriate control charts;
- shifts, when they occur, remain until they are detected and corrective action taken;
- temporal (as opposed to spatial) detection is the critical problem.

However, the general biosurveillance problem violates many, if not all, of these assumptions. For example,

- there is little or no control over disease incidence and thus the distribution of disease incidence is usually nonstationary;
- observations (often daily counts) are autocorrelated, and the need for quick detection works against the idea of taking measurements far enough apart to achieve (near) independence;
- in biosurveillance there is little information on what types of statistics are useful for monitoring—one is often looking for anything that seems unusual;
- because individual observations are being monitored, the idea of asymptotic sampling distributions does not apply, and the data often contain significant systematic effects that must be accounted for;
- outbreaks are transient, with disease incidence returning to its original state once an outbreak has run its course;

- identifying both spatial and temporal deviations is often critical.

This gap between existing SPC methods and the biosurveillance problem provides an area that is ripe for new research.

In spite of the gap, the standard SPC methods are sometimes applied to biosurveillance data with little modification [47,48]) and in some cases, the methods are modified to attempt to account for the autocorrelation. For example, EARS applies variants of the Shewhart control chart (Eq. 1) and 2 below) and a cumulative method (Eq. 3). These methods use various moving windows of data to estimate the process mean and standard deviation [23] and they are intended to be used when little historic (“baseline”) information is available.

The EARS methods are called “C1,” “C2,” and “C3” and are defined as follows [49]: Let $Y(t)$ be the observed count for period t representing, for example, the number of individuals arriving at a particular hospital emergency room with a specific syndrome on day t . The C1 calculates the statistic $C_1(t)$ as

$$C_1(t) = \frac{Y(t) - \bar{Y}_1(t)}{S_1(t)}, \quad (1)$$

where $\bar{Y}_1(t)$ and $S_1(t)$ are the moving sample mean and standard deviation, respectively:

$$\begin{aligned} \bar{Y}_1(t) &= \frac{1}{7} \sum_{j=t-1}^{t-7} Y(j) \\ \text{and } S_1^2(t) &= \frac{1}{6} \sum_{j=t-1}^{t-7} [Y(j) - \bar{Y}_1(j)]^2. \end{aligned}$$

If $S_1^2(t) = 0$, then EARS sets it to a small positive number. As implemented in the EARS system, the C1 signals on day t when the C_1 statistic exceeds a threshold h , which is fixed at three sample standard deviations above the sample mean: $C_1(t) > 3$.

The C2 is similar to the C1, but incorporates a two-day lag in the mean and standard deviation calculations. Specifically, it calculates

$$C_2(t) = \frac{Y(t) - \bar{Y}_3(t)}{S_3(t)}, \quad (2)$$

where

$$\begin{aligned} \bar{Y}_3(t) &= \frac{1}{7} \sum_{j=t-3}^{t-9} Y(j) \\ \text{and } S_3^2(t) &= \frac{1}{6} \sum_{j=t-3}^{t-9} [Y(j) - \bar{Y}_3(j)]^2. \end{aligned}$$

If $S_3^2(t) = 0$, then EARS sets it to a small positive number and the C2 method signals on day t when $C_2(t) > 3$.

The C3 combines current and historical data from day t and the previous two days, calculating the statistic $C_3(t)$ as

The C3 method described above, as implemented in EARS V4.5, is different from the original EARS implementation. See Fricker [45] for a description of the original C3 method.

$$C_3(t) = \sum_{i=t}^{t-2} \max[0, C_2(i) - 1]. \quad (3)$$

It signals when $C_3(t) > 2$. See Fricker [45] for additional description.

BioSense originally implemented the C1, C2, and C3 methods, but has since modified the C2. Calling the new method “W2,” it calculates the mean and standard deviation separately for weekdays and weekends (using the relevant last seven days with a two-day lag). Following the suggestion of Buckeridge *et al.* [40], it uses an empiric method to define the threshold and users of the system can select the threshold as an option [50].

To date, multivariate SPC methods have not been incorporated into operational biosurveillance systems. Some research has been conducted to define and evaluate directional multivariate methods, including Joner *et al.* [51], Fricker [47], and Stoto *et al.* [48]. Whether or not multivariate methods provide additional sensitivity to detect outbreaks as compared to the current practice of using multiple simultaneous univariate methods has yet to be conclusively demonstrated. Various methods have also been proposed to combine and/or adjust for the application of multiple univariate methods in multivariate settings. See the discussion in Rolka *et al.* [52] about parallel

and consensus monitoring methods and Stoto *et al.* [34,48] for a discussion and an evaluation of some of these methods.

Regression and time series methods have also been proposed to explicitly model, and hence account for, seasonality. The basic idea is to model the disease incidence process, perhaps including terms in the model for annual seasonal variations, monthly variations, and even day of the week and holiday variations. The model is then used to either (i) predict the expected number of events and the difference between the expected number and observed number is monitored for excessive deviations or, (ii) model and then remove the explainable/known effects (sometimes called *preconditioning*) and then the residuals are monitored using traditional SPC methods. This is consistent with recommendations by Montgomery [43] for autocorrelated data. Examples in the literature include Brillman *et al.* [53], who apply the CUSUM to the prediction errors, the CDC's cyclical regression models discussed in Hutwagner *et al.* [54], log-linear regression models in Farrington *et al.* [55], and time series models in Reis and Mandl [56]. See Shmueli and Burkom [31] for additional discussion of the use of regression and time series methods for syndromic surveillance and Burkom *et al.* [57] for a comparison of two regression-based methods and an exponential smoothing method applied to biosurveillance forecasting. Also see Lotze *et al.* [58] for a detailed discussion of preconditioning applied to syndromic surveillance data.

Other temporal methods that have been proposed or are in use for syndromic surveillance include wavelets [59–61, and the discussion in Shmueli and Burkom 31]; Bayesian networks [52,62]; hidden Markov models [63]; Bayesian dynamic models [64], and rule-based methods [65].

Spatial and Spatiotemporal Methods

Kleinman *et al.* [66] and Lazarus *et al.* [67] proposed a generalized linear mixed model (GLMM) to simultaneously monitor disease counts over time in a region divided into smaller subareas (zip codes). It is statistically attractive because it uses information

across the entire region while appropriately adjusting for the smaller areas.

As described in Kleinman *et al.* [66], there are two forms of the model depending on whether individual data and covariates are available versus aggregated counts and covariates by zip code. In the former case, the model is

$$E(y_{ijt} | b_i) = p_{ijt} \text{ and } \text{logit}(p_{ijt}) = \mathbf{x}_{ijt}\beta + b_i, \quad (4)$$

where y_{ijt} is an indicator for whether or not person j in area i is a case on day t , p_{ijt} is the probability he or she is a case, $\mathbf{x}_{ijt}$ is a vector of observed covariates on person j and/or area i over time up to and including day t , β is a vector of fixed effects, and b_i is a random effect for area i . When no individual level covariate information is available, the most likely situation, the model is

$$E(y_{it}|b_i) = p_{it} \text{ and } \text{logit}(p_{it}) = \mathbf{x}_{it}\beta + b_i, \quad (5)$$

where $y_{it} = \sum_{j=1}^{n_{it}} y_{ijt}$. In this model, p_{it} can be thought of as the probability that an individual in area i will be a case on day t .

Having fitted the model in Equation (5), z cases are observed on day $t + 1$. The rarity of the observed count is assessed by calculating

$$\Pr(Z \geq z \text{ cases}) = 1 - \sum_{k=1}^{z-1} \binom{n_{it}}{k} \hat{p}_{it}^k (1 - \hat{p}_{it})^{n_{it}-k}, \quad (6)$$

where $\hat{p}_{it}$ is calculated from the estimated coefficients in the usual way for logistic regression and $1/(\hat{p}_{it} \times \# \text{ tests conducted})$ is proposed as the recurrence interval: the number of time periods for which the expected number of counts of z or more cases is one [68]. Waller [69] recommends an alternate calculation for the recurrence interval and Woodall *et al.* [68] take issue with both the use of and recommended calculations for the recurrence interval.

The small area regression and testing (“SMART”) method in BioSense (see the BioSense User Guide [70]) is based on the Kleinman *et al.* [66] and Lazarus *et al.* [67] GLMM approach. However, as implemented

in BioSense, it only uses spatial information to bin data into separate time series, the output of which are subsequently combined using a Bonferroni correction. Hence, the BioSense SMART method is properly classified as a temporal method.

The most commonly used spatial method is the scan statistic, particularly as implemented in the SaTScan software (www.satscan.org). Originally developed to retrospectively identify disease clusters [71], the method is now regularly used prospectively in biosurveillance systems [72]. For example, it was used as part of a drop-in syndromic surveillance system in New York City after the 9/11 attack [73]. While it has been studied by the BioSense program, it has not yet been implemented in the BioSense system interface [74] and the BioSense User Guide [70].

The basic idea in SaTScan is to count the number of cases that occur in a cylinder, where the circle is the geographic base and the height of the cylinder corresponds to time. The cylinder is passed over space, varying the radius of the circle (up to a maximum radius that includes 50% of the monitored population) and the height of the cylinder and counts of cases for those geographic regions whose centroids fall within the circle for the period of time specified by the height of the cylinder are summed. When used for prospective biosurveillance, the start date of the height of the cylinder is varied but the end date is fixed at the most current time period. Conditioning on the expected spatial distribution of observations, SaTScan reports the most likely cluster (in both space and time) and its p -value.

Though widely used, some aspects of the prospective application of the SaTScan methodology have been questioned, particularly the use of recurrence intervals and performance comparisons between SaTScan and other methods. See Woodall *et al.* [68] for further details. Also, see Kulldorff [72] for other methods for disease mapping and for testing whether an observed pattern of disease is due to chance.

Fricker and Chang [75] introduced a new spatiotemporal methodology for biosurveillance called the repeated two-sample rank

(RTR) procedure. It is designed to sequentially incorporate information from individual observations and thus can operate on data in real-time as it arrives into an automated biosurveillance system. In addition, upon a signal of a possible outbreak, the methodology suggests a way to graphically indicate the likely outbreak location, and the output can subsequently be used to track the spread of the outbreak. Thus, the methodology can be used for both, EED and SA in automated biosurveillance systems.

Olson *et al.* [76] and Forsberg *et al.* [77] take an alternate approach to assessing possible disease clusters using M -statistics based on the distribution of pairwise distances between cases. That is, let $\mathbf{X} = \{X_1, \dots, X_n\}$ represent the locations of n cases on the plane and let $\mathbf{d} = \{d_1, \dots, d_{\binom{n}{2}}\}$ be the $\binom{n}{2}$ interpoint distances, then the M -statistic is

$$M = (\mathbf{o} - \mathbf{e})^T \hat{S}^{-1} (\mathbf{o} - \mathbf{e}), \quad (7)$$

where $\mathbf{o}$ and $\mathbf{e}$ are vectors of observed and expected counts of binned interpoint distances and $\hat{S}^{-1}$ is the inverse of the estimate of the covariance matrix. However, Forsberg *et al.* [78] state, "...these methods still require much refinement and further research."

Other approaches to spatial and spatiotemporal biosurveillance methods include the automated epidemiologic geotemporal integrated surveillance system (AEGIS) by Olson *et al.* [76] and the application of CUSUM methods to the spatial distribution of cases [79]. See Lawson and Kleinman [80] for additional exposition and methods, and Mandl *et al.* [15] for further discussion on spatial and spatiotemporal modeling issues. For spatial methods with application to more traditional public health data and problems, see Waller and Gottway [81].

CONCLUSION

Biosurveillance systems are being developed and implemented around the world. They are motivated by a need for improved public health surveillance, not only for bioterrorism,

but also to improve detection and responsiveness to natural disease outbreaks such as H1N1, avian influenza, and SARS, and as such they hold great promise as public health tools. For additional development and discussion, see Fricker [44], Lombardo and Buckeridge [82], M'ikanatha *et al.* [83], Wager *et al.* [84], Waller and Gottway [81], and Stroup *et al.* [85].

BIRTH-AND-DEATH PROCESSES

GUVENÇ DEĞIRMENCI
Department of Industrial
Engineering, University
of Pittsburgh,
Pittsburgh,
Pennsylvania

INTRODUCTION

A birth-and-death (BD) process is a continuous-time Markov chain (CTMC), $\{X(t) : t \geq 0\}$, defined on the countable state space $S = \{0, 1, 2, \dots\}$ and whose transitions are restricted to only its nearest neighbors. In other words, if at any time the process is in state $i \in S \setminus \{0\}$, then in an infinitesimal time interval, it will next transition to either state $i + 1$ or to state $i - 1$. If the current state is 0, then it can only transition to state 1. BD processes have been used to model population dynamics, queueing systems, inventory systems, computer and communications networks, and biological systems, to name only a few. For example, a BD process can be used to describe the temporal and stochastic evolution of the population of a geographical region when the birth and death rates of the region can be estimated from historical data. In such models, the random variable $X(t)$ represents the population of the region at time t . In a queueing context, the BD process can be used to describe the total number of customers in a stochastic service system (i.e., the number of customers currently in service and those waiting to receive service) when customers arrive according to a Poisson process and bring an exponentially distributed service requirement.

The BD process can be analyzed in a transient sense (for any finite t such that $t \geq 0$), or in an asymptotic sense (as $t \rightarrow \infty$). The asymptotic behavior is often used to highlight the salient features of the system's dynamics. Moreover, asymptotic results are often

mathematically tractable, easier to obtain, and serve as reasonable approximations to the transient behavior when t is large. The ergodic theorem for CTMCs gives the conditions under which the limiting distribution of a BD process coincides with the long-run fraction of time that the process occupies any state in S . For instance, in a high-speed communications network, it is important to know the fraction of time each node in the network is in a congested state in order to characterize important delay and congestion measures. When the joint process of buffer content at all the nodes can be modeled as a multivariate BD process, the distribution can be obtained in a simple, closed form. The limiting behavior can also be used to design new systems that satisfy quality-of-service guarantees.

In the remainder of this article, we formally define the standard BD process, review some basic facts about its transient and asymptotic behavior, and discuss some important special cases of the BD process. In addition, we highlight two applications in queueing theory, discuss some extensions, and provide guidance for further reading.

FORMAL MODEL DESCRIPTION

A BD process, $\{X(t) : t \geq 0\}$, is a CTMC on the countable state space $S = \{0, 1, 2, \dots\}$ whose distinguishing characteristic is that it transitions only to its nearest neighbors. Specifically, from any state $i \in S \setminus \{0\}$, the process may transition to state $i - 1$, or to state $i + 1$; however, it may not transition to any state $i \pm k$ where $k \geq 2$. If $i = 0$, it may only transition to $i + 1$. Intuitively, one may think of a BD process as representing the evolution of a population process, and the state, $X(t)$, is the population size at time t . An increase in the population size (by unit increment) represents a "birth" and a decrease (by unit decrement) represents a "death." If the birth and/or death rates depend on the current population, then the BD process is called *state dependent*. In other words, whenever $X(t) = i$,

the birth rate is a positive number λ_i , and the death rate is μ_i , $i \in S$.

For any $s, t \geq 0$ and $i, j \in S$, the transition probability functions of a BD process are given by

$$p_{ij}(s, t) \equiv \mathbb{P}(X(t + s) = j | X(s) = i),$$

and the BD process is called *time-homogeneous* if $p_{ij}(s, t) = p_{ij}(0, t) =: p_{ij}(t)$ for any $s \geq 0$. For $i > 0$, and a small interval of length t , the transition functions of the time-homogeneous version satisfy the following equations:

$$p_{ij}(t) = \begin{cases} \lambda_i t + o(t), & j = i + 1, \\ \mu_i t + o(t), & j = i - 1, \\ 1 - (\lambda_i + \mu_i)t + o(t), & j = i, \\ o(t), & \text{otherwise,} \end{cases}$$

where $o(t)/t \rightarrow 0$ as $t \rightarrow 0$. These probabilities are interpreted as follows. Given that the current state is i ($i > 0$), in an infinitesimal time interval, the next event is either a birth with probability $\lambda_i t + o(t)$ or a death with probability $\mu_i t + o(t)$, and the population size remains the same with probability $1 - (\lambda_i + \mu_i)t + o(t)$. The probability that a “jump” magnitude exceeds unity is of order $o(t)$. Practically speaking, in a small interval of time, multiple births, multiple deaths, and simultaneous births and deaths do not occur. Whenever $i = 0$, the process next transitions to state 1 after an exponentially distributed amount of time with mean $1/\lambda_0$. It is not hard to see that the *infinitesimal transition rates* of the process are given by the birth rates $\{\lambda_i\}$ and the death rate $\{\mu_i\}$. The transition rate diagram of this CTMC is depicted in Fig. 1.

The infinitesimal generator matrix of the BD process, denoted by $\mathbf{Q}$, is given by

$$\mathbf{Q} = \begin{bmatrix} -\lambda_0 & \lambda_0 & 0 & 0 & 0 \dots \\ \mu_1 & -(\lambda_1 + \mu_1) & \lambda_1 & 0 & 0 \dots \\ 0 & \mu_2 & -(\lambda_2 + \mu_2) & \lambda_2 & 0 \dots \\ 0 & 0 & \mu_3 & -(\lambda_3 + \mu_3) & \lambda_3 \dots \\ \vdots & \vdots & \vdots & \ddots & \ddots \end{bmatrix}, \quad (1)$$

which is seen to possess a tridiagonal structure. This structure provides some computational advantages, particularly when evaluating the asymptotic behavior of the process (as $t \rightarrow \infty$). The transition functions, $p_{ij}(t)$, can be shown to satisfy the Kolmogorov backward equations, a set of ordinary differential equations given by

$$\frac{dp_{ij}(t)}{dt} = \begin{cases} \lambda_0 [p_{1j}(t) - p_{ij}(t)], & i = 0, \\ \lambda_i p_{i+1,j}(t) + \mu_i p_{i-1,j}(t) - (\lambda_i + \mu_i) p_{ij}(t), & i > 0. \end{cases}$$

Suppose we let $\mathbf{P}(t) = [p_{ij}(t)]$, $i, j \in S$, denote the matrix of transition functions for any $t \geq 0$. Obtaining $\mathbf{P}(t)$ for a generic CTMC with finite state space S is not too difficult. The Kolmogorov backward equations can be written in a convenient matrix form as follows:

$$\frac{d\mathbf{P}(t)}{dt} = \mathbf{Q} \mathbf{P}(t).$$

This (matrix) differential equation has the obvious solution

$$\mathbf{P}(t) = \mathbf{P}(0) \exp(\mathbf{Q}t), \quad t \geq 0,$$

where $\exp(\mathbf{A})$ denotes matrix exponentiation of the matrix $\mathbf{A}$, and $\mathbf{P}(0) = I$, the identity matrix. Hence, $\mathbf{P}(t)$ can be obtained by employing any number of numerical routines for performing matrix exponentiation.

Figure 1. Transition rate diagram of a standard birth-and-death process.

However, because the BD process is defined on $S = \{0, 1, 2, \dots\}$, solving for the transition functions is generally challenging except in a few special cases. For instance, if $\{X(t) : t \geq 0\}$ is a homogeneous Poisson process with $\lambda_i = \lambda$ and $\mu_i = 0$ for all $i \in S$, then the Kolmogorov backward equations can be solved exactly using standard Laplace transform techniques (cf. Kulkarni [1]). For a general BD process (with state-dependent births and deaths), the method of continued fractions has been successfully applied to analyze the transient behavior. Three representative examples of the use of continued fractions in analyzing BD processes are given in Parthasarathy [2–4]. Uniformization methods can also be used, particularly if the state space can be truncated at a finite level [1,5].

Some Special Cases

It is easy to see that some well-known stochastic processes are special cases of the standard BD process. Specifically, if $\mu_i = 0$ for all $i \in S$, then $\{X(t) : t \geq 0\}$ is called a *pure birth process*. In case $\mu_i = 0$ and $\lambda_i = \lambda$ for all $i \in S$, the BD process is a homogeneous Poisson process (see **Poisson Process and its Generalizations**). A prototypical example of the pure birth process is cell reproduction where $X(t)$ is the number of cells living in a colony at time t . Each cell in the colony acts independent of the others and splits into two cells after an exponentially distributed amount of time with parameter λ . Therefore, the birth rates are $\lambda_i = i\lambda$, $i \in S$, since each of the i members gives birth with the same exponential rate λ . In this case, $\{X(t) : t \geq 0\}$ is called a *Yule process*.

A *pure death process* is a BD process with $\lambda_i = 0$ for all $i \in S$ (i.e., only deaths occur until the process is absorbed at state 0). For example, consider a machine that operates initially with i ($i > 0$) components in parallel such that each component has an exponentially distributed lifetime with mean $\mu^{-1} < \infty$, and suppose $X(t)$ denotes the number of functioning components at time t . The component lifetimes are assumed to be mutually independent, and the system can continue to function as long as at least one component is functioning. At the time of a

component failure, the system state is decremented by unity, and the failed component cannot be repaired. Here, the death rates are given by $\mu_i = i\mu$, $i \in S$, since each component fails at the same exponential rate μ .

LIMITING BEHAVIOR

In this section, we discuss the limiting behavior of the transition probabilities $p_{ij}(0, t)$ as $t \rightarrow \infty$. Initially, let us assume the existence of a set of values, $\{p_j : j \in S\}$, such that

$$\begin{aligned} \lim_{t \rightarrow \infty} p_{ij}(0, t) &= \lim_{t \rightarrow \infty} \mathbb{P}(X(t) = j | X(0) = i) \\ &= p_j, \quad j \in S, \end{aligned} \quad (2)$$

and note that p_j is independent of the initial state i . If the limit in Equation (2) exists, then the row vector $\mathbf{p} \equiv (p_0, p_1, p_2, \dots)$ is called the *limiting distribution* of $\{X(t) : t \geq 0\}$. The existence of the limit is ensured when $\{X(t) : t \geq 0\}$ is irreducible (i.e., all states in S communicate) and positive recurrent (i.e., starting from any state, the expected time to return to that state is finite). The following result from the asymptotic analysis of positive recurrent CTMCs shows how to obtain the limiting distribution $\mathbf{p}$.

Theorem 1. *If $\{X(t) : t \geq 0\}$ is an irreducible and positive recurrent CTMC, then its limiting distribution $\mathbf{p}$ exists and is the unique positive solution to the system of equations*

$$\mathbf{p}\mathbf{Q} = \mathbf{0}; \quad \sum_{j \in S} p_j = 1, \quad (3)$$

where $\mathbf{0}$ denotes the zero vector.

Whenever these probabilities exist, the BD process is said to be *ergodic*, and the limit in Equation (2) has two important interpretations. First, by definition, p_j is the limiting probability that the process $\{X(t) : t \geq 0\}$ is in state j . Second, p_j can be interpreted as the long-run proportion of time that the process spends in state j . For the BD process, the matrix $\mathbf{Q}$ takes the form of Equation (1).

Solving the system of equations (3) for the BD process, it is not difficult to see that

$$p_k = p_0 \left[\prod_{i=0}^{k-1} \frac{\lambda_i}{\mu_{i+1}} \right], \quad k \geq 1. \quad (4)$$

Applying the normalization condition,

$$\sum_{k=0}^{\infty} p_k = 1,$$

the probability p_0 is obtained by

$$p_0 = \left[1 + \sum_{k=1}^{\infty} \prod_{i=0}^{k-1} \frac{\lambda_i}{\mu_{i+1}} \right]^{-1}. \quad (5)$$

Equation (4) shows that each of the probabilities depends explicitly on the limiting probability p_0 that the process is in state 0. Hence, the limiting distribution exists if and only if $p_0 > 0$, that is, if

$$\sum_{k=1}^{\infty} \frac{\lambda_0 \lambda_1 \cdots \lambda_{k-1}}{\mu_1 \mu_2 \cdots \mu_k} < \infty.$$

Hence, the ergodicity of the process depends explicitly on the convergence of the above infinite series. Should the series diverge to $(+\infty)$, then $p_0 = 0$ and a limiting distribution does not exist.

APPLICATIONS IN QUEUEING THEORY

BD processes are commonly used to model Markovian queueing systems. Here, we discuss the application of BD processes in two of the most basic queueing systems.

The $M/M/1$ Queue

In the $M/M/1$ queueing system, customers arrive according to a Poisson process with rate λ , and each customer brings a service requirement that is exponentially distributed with parameter μ . The system has only a single server for processing customers, and it has an infinite waiting room for customers to wait for service (see **The $M/M/1$ Queue** for further details). Let $X(t)$ denote the number of customers in the system at time t (i.e., in

service or in the waiting area) and note that $\{X(t) : t \geq 0\}$ is a BD process with constant birth and death rates $\lambda_j = \lambda$ for $j \geq 0$ and $\mu_j = \mu$ for $j \geq 1$, respectively. The ratio of the arrival rate to the service rate is the traffic intensity given by $\rho = \lambda/\mu$. Then using Equations (4) and (5), we obtain

$$p_0 = \left[1 + \sum_{k=1}^{\infty} \left(\frac{\lambda}{\mu} \right)^k \right]^{-1}.$$

The infinite series converges if and only if $\rho < 1$; therefore, the system is stable if and only if $\lambda < \mu$. In such a case, the limiting probabilities are given by

$$p_k = p_0 \left(\frac{\lambda}{\mu} \right)^k = (1 - \rho) \rho^k, \quad k \geq 1.$$

The $M/M/s$ Queue

The $M/M/s$ is similar to the $M/M/1$ queue except that it has s ($s \geq 1$) independent and identical servers (see **The $M/M/s$ Queue**). Since there are s servers, the death rates of this BD process are given by

$$\mu_j = \begin{cases} j\mu, & \text{if } j < s, \\ s\mu, & \text{if } j \geq s. \end{cases}$$

The traffic intensity for this system is $\rho = \lambda/s\mu$. Using Equations (4) and (5), the limiting probabilities are given by

$$p_k = \begin{cases} p_0 \frac{(s\rho)^k}{k!}, & 0 \leq k \leq s, \\ p_0 \frac{\rho^k s^s}{s!}, & k \geq s. \end{cases}$$

and

$$p_0 = \left[\sum_{k=0}^{s-1} \frac{(s\rho)^k}{k!} + \frac{(s\rho)^s}{s!} \frac{1}{1 - \rho} \right]^{-1}.$$

Therefore, the limiting distribution of the number of customers in the system exists if $\rho < 1$, that is, if $\lambda < s\mu$. This means that the maximum service rate must exceed the arrival rate of customers for the system to remain stable.

EXTENSIONS AND FURTHER READING

An important extension of the BD process is the quasi-birth-and-death (QBD) process [6–8]. The QBD is a bivariate Markov process on the state space $S = \{(i, j) : i \geq 0, 1 \leq j \leq M_i\}$, ($0 < M_i < \infty$), where i is the *level* of the process and j is referred to as the *phase*. Its block tridiagonal infinitesimal generator matrix is given by

$$\mathbf{Q} = \begin{bmatrix} A_1^{(0)} & A_0^{(0)} & 0 & 0 & 0 & \dots \\ A_2^{(1)} & A_1^{(1)} & A_0^{(1)} & 0 & 0 & \dots \\ 0 & A_2^{(2)} & A_1^{(2)} & A_0^{(2)} & 0 & \dots \\ 0 & 0 & A_2^{(3)} & A_1^{(3)} & A_0^{(3)} & \dots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}.$$

The positive integer M_i is the number of phases at the i th level. The QBD process is called *level independent* if, for $i \geq 0$, $M_i = M$, $A_0^{(i)} = A_0$ and for $i \geq 1$, $A_1^{(i)} = A_1$ and $A_2^{(i)} = A_2$ (see **Level-Independent Quasi-Birth-and-Death Processes**). Otherwise, the QBD process is called *level dependent* (see **Level-Dependent Quasi-Birth-and-Death Processes**). The analysis of QBDs is facilitated by the matrix-geometric method, developed primarily by Neuts [6]. By employing matrix-geometric methods, many researchers have addressed the transient and asymptotic analysis of (level-independent) QBD processes, as well as their many and varied applications. A method for computing the stationary distribution in the level-dependent case is given in Bright and Taylor [9].

The multivariate generalization of a BD process is called a *Markov population process* [10]. Let S^m be the set of all m -dimensional vectors $\mathbf{v} = (v_1, v_2, \dots, v_m)$ whose components $v_k \in S$, $1 \leq k \leq m$ are nonnegative integers. Intuitively, one may think of $\mathbf{v}$ as the population vector of a system consisting of m colonies with v_k as the population of the k th colony. Let u and ω be indicator variables such that $u = 1$ ($\omega = 1$), if there is an arrival to (departure from) the k th colony. For any $s, t \geq 0$ and $v_k \in S$, $1 \leq k \leq m$, the transition probability functions of a Markov population

process are given by

$$\mathbb{P}(\mathbf{X}(s+t) = \mathbf{v} + u\mathbf{e}_k - \omega\mathbf{e}_l | \mathbf{X}(s) = \mathbf{v}) = \begin{cases} \lambda_k(\mathbf{v})t + o(t), & u=1, \omega=0, \\ \mu_l(\mathbf{v})t + o(t), & u=0, \omega=1, \\ \gamma_k(\mathbf{v})t + o(t), & u=\omega=1, \\ 1 - [\sum_k \lambda_k(\mathbf{v}) + \sum_l \mu_l(\mathbf{v}) \\ + \sum_k \sum_l \gamma_{kl}(\mathbf{v})]t + o(t), & u=\omega=0, \\ o(t), & \text{otherwise,} \end{cases}$$

where $o(t)/t \rightarrow 0$ as $t \rightarrow 0$ and $\mathbf{e}_k$ is the k th unit vector. The transition from state $\mathbf{v}$ to $\mathbf{v} + \mathbf{e}_k$ may be described as an arrival to the k th colony, the transition from $\mathbf{v}$ to $\mathbf{v} - \mathbf{e}_k$ as a departure from k , and the transition from $\mathbf{v}$ to $\mathbf{v} + \mathbf{e}_k - \mathbf{e}_l$ as a transfer from l to k , $l \neq k$ (assuming $m \geq 2$). For certain classes of Markov population processes, Kingman [10] obtained the equilibrium distributions as $t \rightarrow \infty$. The reader is referred to McNeil and Schach [11], Barbour [12], and Klebaner [13] for further details on this subject.

One of the earliest descriptions of the BD process, its practical implications, and the limiting distribution were provided by Feller [14]. Classical textbooks that provide further details include Ross [15], Kulkarni [1], and Asmussen [16]. Properties of the BD process and its transient analysis are described in Karlin and McGregor [17–19] and more recently by Jouini and Dallery [20]. The BD process has been extended to include more complex dynamics. For instance, Kendall [21] developed the non-Markovian birth process. Age-dependent BD processes are analyzed by Waugh [22] and Weiner [23]. Griffiths [24,25] analyzed bivariate and multivariate BD processes and discussed transient properties. The BD process with immigration and emigration is studied by Zheng *et al.* [26], Swift [27], and Aksland [28]. Karlin and Tavar [29], and van Doorn and Zeifman [30] analyzed the BD process with killing.

BLOCK REPLACEMENT POLICIES

University of Arizona,
Tucson, Arizona

Block replacement policies arise in the context of reliability theory, where the interest is focused on the random time to fail of a unit or a system [1]. In this context, preventive maintenance of units or systems are used to reduce the number of failures for fixed interval times or to increase the time to failure in some stochastic sense. Block replacement policies are among the most commonly used planned replacement policies. Under a block replacement policy, a unit is replaced upon failure and additionally at times $T, 2T, 3T, \dots$. Therefore replacements are scheduled in advance and they make up a simple preventive maintenance program. Several issues have been considered for block replacement policies. In this article, we consider results for the comparison of block replacement policies with alternative preventive maintenance policies. More precisely, we consider conditions under which the number of unplanned failures (or the time at which unplanned failures occur) are reduced (increased) under a block replacement policy compared with some other preventive maintenance policies. Further extensions of the usual block replacement policy and cost analysis are also discussed in this article.

In this article, “increasing” and “decreasing” stand for “nondecreasing” and “nonincreasing,” respectively.

UNIVARIATE COMPARISONS WITH OTHER REPLACEMENT POLICIES

Throughout this article, unless stated otherwise, we will consider a unit or a

system which is subject to failures and we will denote by X , the random time to failure. Under a block replacement policy, the unit is replaced by a new one upon failure and at times $T, 2T, 3T, \dots$. Let us denote by $N_T^B \equiv \{N_T^B(t), t \geq 0\}$, the counting process that counts the number of failures or unplanned replacements, that is, $N_T^B(t)$ denote the number of failures in the interval $[0, t]$. The arrival times at which the n th failure occurs will be denoted by $S_{n,T}^B$. Given that the block replacement policy is introduced to reduce the number of unplanned failures, it is natural to compare this policy with the usual replacement policy in which a unit is replaced by a new one only upon failure and no other replacements are considered. This leads to a renewal process which will be denoted by $N \equiv \{N(t), t \geq 0\}$, where $N(t)$ denotes the number of failures in the interval $[0, t]$ and the arrival times at which the n th failure occurs will be denoted by S_n . The renewal function for this process will be denoted by $M(t) \equiv E[N(t)]$ (see *Definition and Examples of Renewal Processes* and *Renewal Function and Renewal-Type Equations*).

The natural framework where the comparisons can be stated is the context of stochastic orders and aging notions. These provide several tools for the purpose of stochastically comparing random quantities and describe the aging process of the units or systems that are involved in the maintenance.

First, we recall several notions of stochastic orders that will be used in the sequel; for general references on the subject the reader can look at Refs 2 and 3 as well as *Aging, Characterization, and Stochastic Ordering*.

Let X and Y be two absolutely continuous nonnegative random variables. The random variable X is said to be smaller than the random variable Y in the ordinary stochastic order (denoted as $X \leq_{\text{st}} Y$) if $P(X > x) \leq P(Y > x)$ for all x . Thus, the comparison in the ordinary stochastic order indicates that in some stochastic sense, the random variable Y tends to take on larger values than the

random variable X . Additionally, the stochastic order can be characterized as follows: $X \leq_{\text{st}} Y$ if, and only if, $E[\phi(X)] \leq E[\phi(Y)]$ for all increasing functions ϕ for which previous expectations are defined. Therefore, the stochastic order not only compares random lifetimes in terms of survival probabilities but also in terms of expected values of increasing transformations such as expected utilities, benefits, or costs, associated with the random lifetimes.

In case the transformation ϕ is increasing and convex, this leads to a weaker comparison. The random variable X is said to be smaller than the random variable Y in the increasing convex order (denoted as $X \leq_{\text{icx}} Y$) if $E[\phi(X)] \leq E[\phi(Y)]$ for all increasing convex functions ϕ for which the expectations are defined.

Another possibility is to compare the Laplace transforms. The random variable X is said to be smaller than the random variable Y in the Laplace transform order (denoted as $X \leq_{\text{Lt}} Y$), if $E[\exp\{-sX\}] \geq E[\exp\{-sY\}]$ for all $s > 0$.

The following implications hold among the above notions:

$$\begin{array}{ccc} X \leq_{\text{st}} Y & \Rightarrow & X \leq_{\text{icx}} Y \\ \Downarrow & & \Downarrow \\ X \leq_{\text{Lt}} Y & \Rightarrow & E[X] \leq E[Y]. \end{array}$$

Next, we recall some aging notions. Let X be a nonnegative, absolutely continuous random variable. Denote by F and f , its distribution and density functions, respectively.

The random variable X is said to have the aging property of increasing failure rate (IFR) if $1 - F$ is logconcave. It has the property of decreasing failure rate (DFR) if $1 - F$ is logconvex on its support. Denoting the hazard rate function of X by $r \equiv f/(1 - F)$, it holds that X is IFR [or DFR] if, and only if r is increasing [or decreasing].

The random variable X is said to be new better than used (NBU) [or, new worse than used (NWU)] if, and only if, $X \geq_{\text{st}} [X - t | X > t]$ for all $t > 0$. Another characterization of this aging class can be given in terms of $-\log(1 - F)$, that is, X is NBU [NWU], if and only if, $-\log(1 - F)$ is a superadditive [subadditive] function, where we say that a

function ϕ is superadditive [subadditive], if $\phi(x + y) \geq [\leq] \phi(x) + \phi(y)$ for all $x, y \geq 0$.

The random variable X is said to be new better than used in the convex order (NBUC), if $X \geq_{\text{icx}} [X - t | X > t]$ for all $t > 0$.

The random variable X is said to be new better than used in the Laplace transform order (NBUL) if $X \geq_{\text{Lt}} [X - t | X > t]$ for all $t > 0$.

Finally, the random variable X with a finite mean is said to be new better than used in expectation (NBUE) if $E[X] \geq E[X - t | X > t]$ for all $t \geq 0$.

Among these aging notions, we have the following relationships:

$$\begin{array}{ccccc} \text{IFR} & \Rightarrow & \text{NBU} & \Rightarrow & \text{NBUC} \\ & & \Downarrow & & \Downarrow \\ & & \text{NBUL} & \Rightarrow & \text{NBUE}. \end{array}$$

The first result in the literature that stochastically compares maintenance policies was provided by Barlow and Proschan [4]; it states that under the IFR assumption we have $N_T^B(t) \leq_{\text{st}} N(t)$ for all $t \geq 0$. The result was improved by Marshall and Proschan [5], replacing the IFR assumption by the weakest NBU assumption and states the following.

Theorem 1. *The comparison $N_T^B(t) \leq_{\text{st}} [\geq_{\text{st}}] N(t)$ holds for all $t \geq 0$ and $T > 0$, if, and only if, X is NBU [NWU].*

This result tells us that NBU [NWU] distributions make up the largest class for which any block replacement policy reduces [increases], in the sense of the ordinary stochastic order, the number of failures in any interval $[0, t]$ compared with a usual replacement policy. Marshall and Proschan [5] also proved the following result—it shows that NBU [NWU] distributions also make up the largest class for which an increase in the frequency of block replacements stochastically reduces [increases] the number of unplanned replacements in any interval $[0, t]$.

Theorem 2. *The comparison $N_{kT}^B(t) \leq_{\text{st}} [\geq_{\text{st}}] N_{kT}^B(t)$ holds for all $t \geq 0$, $T > 0$, and $k = 1, 2, \dots$, if, and only if, X is NBU [NWU].*

From Theorem 1 and the definition of the ordinary stochastic order, it is clear that if X is NBU [NWU] then $E[N_T^B(t)] \leq [\geq] M(t)$ for all $t \geq 0$ and $T > 0$. Shaked and Zhu [6], in the next theorem, provided a characterization of the comparison of expected number of failures in terms of the superadditivity of the renewal function. That is, superadditivity [subadditivity] of M is a necessary and sufficient condition for the practically useful comparisons $E[N_T^B(t)] \leq [\geq] M(t)$ and $E[N_T^B(t)] \leq [\geq] E[N_{kT}^B(t)]$.

Theorem 3. *The following statements are equivalent:*

- (i) $M(t)$ is superadditive [subadditive].
- (ii) $E[N_T^B(t)] \leq [\geq] M(t)$ for all $t \geq 0$ and $T > 0$.
- (iii) $E[N_T^B(t)] \leq [\geq] E[N_{kT}^B(t)]$ for all $t \geq 0$, $T > 0$, and $k = 1, 2, \dots$

Shaked and Zhu [6] also stated the following result, which relates the monotonicity in T of the expected number of failures with the concavity (convexity) of the renewal function. Note that convexity [concavity] is a stronger condition than superadditivity [subadditivity], and under this condition on M , the practically useful fact that $E[N_T^B(t)]$ is increasing [decreasing] in T is obtained.

Theorem 4. *The following statements are equivalent:*

- (i) $M(t)$ is convex [concave].
- (ii) $E[N_T^B(t)]$ is increasing [decreasing] in $T > 0$ for each fixed $t \geq 0$.

If we consider the monotonicity in T , in the stochastic order of $N_T^B(t)$, then Ref. 6 provided the following interesting result, which indicates that the practically useful comparison $N_{T_1}^B(t) \leq_{\text{st}} [\geq_{\text{st}}] N_{T_2}^B(t)$ holds only for some IFR [DFR] lifetimes.

Theorem 5. *If $N_{T_1}^B(t) \leq_{\text{st}} [\geq_{\text{st}}] N_{T_2}^B(t)$ for all $0 < T_1 \leq T_2$, for each fixed $t \geq 0$, then X is IFR [DFR].*

The reversed implication is not true for IFR distributions (counterexample given in Ref. 6), but for DFR distributions it is still unknown if the reversed implication holds. In this case, Brown [7] proved that if X is DFR then $M(t)$ is concave, and therefore from Theorem 4, we have the following practically useful result for DFR lifetimes.

Theorem 6. *If X is DFR then $E[N_T^B(t)]$ is decreasing in $T > 0$ for each fixed $t \geq 0$.*

From Theorem 1, we can also have comparisons of the times in which unplanned replacements occur. Given any counting process $C = \{C(t), t \geq 0\}$, with arrival times $C_n = \inf\{t : C(t) > n\}$, then $\{C(t) < n\} \Leftrightarrow \{C_n > t\}$. From this observation we have under the NBU [NWU] assumption, that $S_n \leq_{\text{st}} [\geq_{\text{st}}] S_{n,T}^B$ for all $n = 1, 2, \dots$

Along these lines, several authors have provided additional results under weaker aging properties.

For instance, the following result follows from results in Yue and Cao [8], and it indicates a useful weak condition under which S_n and $S_{n,T}^B$ can be compared.

Theorem 7. *If X is NBUL then $S_n \leq_{\text{Lt}} S_{n,T}^B$ for all $T > 0$ and $n = 1, 2, \dots$*

If we replace the NBUL assumption in Theorem 7 by the NBUC, we have the following result that was provided by Belzunce *et al.* [9]. This result indicates another useful weak condition under which S_n and $S_{n,T}^B$ can be compared.

Theorem 8. *If X is NBUC then $S_n \leq_{\text{icx}} S_{n,T}^B$ for all $T > 0$ and $n = 1, 2, \dots$*

Under an even weaker condition, we can compare the expected values of S_n and $S_{n,T}^B$. That is, under the NBUE assumption we have the following result by Belzunce *et al.* [10].

Theorem 9. *If X is NBUE then $E[S_n] \leq E[S_{n,T}^B]$ for all $T > 0$ and $n = 1, 2, \dots$*

The block replacement policy can also be compared with the age replacement policy

(see **Age Replacement Policies**). Under an age replacement policy, a unit is replaced upon failure or at age T , whichever comes first. Let $N_T^A(t)$ denote the number of failures in $[0, t]$ under an age replacement policy. It is of practical interest to be able to tell when $N_T^B(t)$, $N_T^A(t)$, and $N(t)$ can be compared. Barlow and Proschan [4] obtained the following result.

Theorem 10. *If X is IFR then $N_T^B(t) \leq_{\text{st}} N_T^A(t) \leq_{\text{st}} N(t)$ for all $t \geq 0$ and $T > 0$.*

On the other hand, Block *et al.* [11] showed the following result for DFR random variables.

Theorem 11. *If X is DFR then $N_T^B(t) \geq_{\text{st}} N_T^A(t)$ for all $t \geq 0$ and $T > 0$.*

FURTHER EXTENSIONS AND COMPARISONS WITH OTHER MAINTENANCE POLICIES

In this section, we consider some extensions of the usual block replacement policy and provide additional comparisons of entire processes instead of just univariate comparisons, as were considered in the previous section.

The block replacement policy has been mainly extended in three directions in the literature. First note that in the usual block replacement policy, when the unit fails it is repaired by replacing the failed unit with a new one which leads to a renewal process, but one can consider a different type of repair, and therefore, consider a different counting process $C \equiv \{C(t), t \geq 0\}$ which describes the times at which the repairing of unplanned failures occur. A second common extension is to consider that planned replacements occur at times $Z = \{z_1, z_2, \dots, z_n, \dots\}$ with $z_n \rightarrow \infty$. The list Z is often called *block* or *replacement schedule*. In the usual block replacement policy $z_n = nT$. At the end of this section, we also mention a third possible generalization which is to consider that the units in use are not identically distributed.

Following Block *et al.* [12,13], and especially Block and Savits [14], we start by describing how to construct, from an arbitrary counting process, a general

stochastic process that takes into account the underlying block replacement schedule. First, we fix the following notation. For an interval I of the form $[a, b]$, $[a, b)$, or $[a, \infty)$, we will denote by $S(I)$ the set of all right-continuous step-functions from I into the nonnegative integers, which start at zero and only increase by jumps of size one. Let us consider the sequence of numbers $0 = z_0 < z_1 < z_2 < \dots < z_n < \dots$, with $z_n \rightarrow \infty$, which represent the times at which planned replacements are going to be done, and let us denote by $C \equiv \{C(t), t \geq 0\}$, the counting process which describes the times at which the repairing of unplanned failures occur under the above-block replacement schedule. Next define the mapping

$$\Psi : \prod_{n=1}^{\infty} E_n \rightarrow S([0, \infty)),$$

where $E_n = S([0, z_n - z_{n-1}])$, by

$$\Psi(s_n)(t) = \begin{cases} s_1(t), & \text{if } 0 \leq t < z_1; \\ \sum_{j=1}^{i-1} s_j(z_j - z_{j-1}) + s_i(t - z_{i-1}), & \text{if } z_{i-1} \leq t < z_i; \end{cases}$$

where $s_n \in E_n$. Now we can construct a new counting process based on C , denoted by $C(Z)$, by setting $C(Z) = \Psi(C_n)$, where $C_n \equiv \{C_n(t), 0 \leq t \leq z_n - z_{n-1}\}$ are independent and identical copies of the counting process C restricted to the corresponding intervals $[0, z_n - z_{n-1}]$. The idea behind this construction is the following: until the time of the first planned replacement z_1 , the number of unplanned repairs is governed by the counting process C . Once the first planned replacement occurs, the counting process is restarted at time 0 and counts the number of unplanned repairs between the time of the first planned repair z_1 and z_2 , and so on.

At some points in the discussion that follows, we will replace the counting process C by the renewal process N considered in the previous section; this generates the new process $N(Z)$, which counts the number of unplanned repairs under a replacement

policy and planned replacements at times $z_1, z_2, \dots$. At other places in the discussion below, we will replace C by a nonhomogeneous Poisson process (see **Poisson Process and its Generalizations**). We note that nonhomogeneous Poisson processes arise in the context of reliability theory, when a minimal repair policy is utilized. Under a minimal repair policy, when a unit fails, the unit is restored to its working condition just prior to the failure. That is, if the unit fails at time t and is minimally repaired then, the time until its next failure (provided it occurs before the next block schedule instance) is stochastically the same as $[X - t | X > t]$ [15,16]. The counting process $N_m \equiv \{N_m(t), t \geq 0\}$ which counts the number of minimal repairs in any interval, is a nonhomogeneous Poisson process with mean function $E[N_m(t)] = -\log P(X > t)$. In the previous construction, if we replace the counting process C by a minimal repair process, then we have the counting process $N_m(Z)$ which counts the number of unplanned repairs under a minimal repair policy and planned replacements at times $z_1, z_2, \dots, z_n, \dots$.

In order to provide results for the comparison of entire processes, we recall two notions that allow us to compare random vectors and stochastic processes.

Given two n -dimensional random vectors $\mathbf{X}$ and $\mathbf{Y}$, the random vector $\mathbf{X}$ is said to be smaller than the random vector $\mathbf{Y}$ in the multivariate stochastic order (denoted as $\mathbf{X} \leq_{\text{st}} \mathbf{Y}$), if $E[\phi(\mathbf{X})] \leq E[\phi(\mathbf{Y})]$ for all increasing functions $\phi: \mathbb{R}^n \rightarrow \mathbb{R}$ for which previous expectations exist.

Furthermore, given two stochastic processes $C \equiv \{C(t), t \geq 0\}$ and $D \equiv \{D(t), t \geq 0\}$, the stochastic process C is said to be smaller than the stochastic process D in the ordinary stochastic order (denoted by $C \leq_{\text{st}} D$) if for all choices of an integer n and $0 \leq t_1 < t_2 < \dots < t_n \in \mathbb{R}$, we have

$$(C(t_1), C(t_2), \dots, C(t_n)) \leq_{\text{st}} (D(t_1), D(t_2), \dots, D(t_n)).$$

The following theorem gives several results which stochastically compare, as described above, the replacement policies discussed above and the ones considered in

the previous section. These results can be found in the papers by Block *et al.* [12–14]. They indicate various potentially useful stochastic comparisons, of the counting processes of unplanned replacements, when the item lifetime is NBU [NWU].

Theorem 12. *If X is NBU [NWU] then for any $Z = \{z_1, z_2, \dots, z_n, \dots\}$, where $0 < z_1 < z_2 < \dots < z_n < \dots$, we have the following comparisons:*

- (i) $N(Z) \leq_{\text{st}} [\geq_{\text{st}}] N$,
- (ii) $N(Z) \leq_{\text{st}} [\geq_{\text{st}}] N_m(Z)$,
- (iii) $N(Z) \leq_{\text{st}} [\geq_{\text{st}}] N_m$,
- (iv) $N_m(Z) \leq_{\text{st}} [\geq_{\text{st}}] N_m$.

If any of the (nonparenthesized) inequalities in (i), (iii), and (iv) above hold for all block replacement schedules Z , then X is NBU. It is not known if this is also the case for (ii).

The results in Theorem 12 were extended to more general settings in Ref. 17. They derived a host of comparisons of replacement policies via the general theory of point processes. Another extension, where the repair upon failure is imperfect, was obtained in Refs 18 and 19.

It is also natural to consider in which sense different sets of times for planned replacement (that is, different block replacement schedules) modify the underlying stochastic processes. Some results in this vein were given by Block *et al.* [12]. Before stating them, we need to recall the definition of refinement. Given two block replacement schedules $Z = \{z_1, z_2, \dots, z_n, \dots\}$ and $V = \{v_1, v_2, \dots, v_n, \dots\}$, where $0 < z_1 < z_2 < \dots < z_n < \dots$ and $0 < v_1 < v_2 < \dots < v_n < \dots$, we say that V is a refinement of Z if $V \supset Z$. If V and Z are different sets of times for planned replacements, then a refinement of a block policy results in the addition of new times of planned replacements. With this notion we have the following results. They can be found in Refs 12, 13, and 20.

Theorem 13. *The random variable X is NBU, if and only if, any one of the following equivalent conditions holds:*

- (i) $N(V) \leq_{\text{st}} N(Z)$ for every $V \supset Z$.

(ii) $N_m(V) \leq_{\text{st}} N_m(Z)$ for every $V \supset Z$.

Again, it is worthwhile to mention that Shaked and Szekli [17] derived some variations of Theorem 13. For example, if X in Theorem 13 is IFR, rather than just NBU, then Shaked and Szekli [17] obtained stronger comparisons between $N(V)$ and $N(Z)$, and between $N_m(V)$ and $N_m(Z)$, than the comparisons given in Theorem 13. Another extension, where the repair upon failure is imperfect, was obtained by Li and Shaked [18]. In the latter paper, the authors also showed for the process that counts the failures under block replacement policy with imperfect repair, that it is monotone with respect to the order $\leq_{\text{st}}$ as a function of the quality of the imperfect repair procedure.

It is possible to provide additional results if we replace the unit under a block replacement policy, with random lifetime X , by another one with random lifetime Y . In this case, we want to denote the dependence of the resulting processes on the distribution functions of X and Y . Thus, for the processes $N(Z)$ and $N_m(Z)$, when the underlying random variable X has the distribution function F , we will write $N(Z, F)$ and $N_m(Z, F)$. Whereas, when the underlying random variable Y has the distribution function G , then we will write $N(Z, G)$ and $N_m(Z, G)$, respectively. For this case, we have the following result by Block *et al.* [12]. Again, these results give a condition under which some useful comparisons of counting processes of unplanned replacements can be made.

Theorem 14. *The random variables X and Y satisfy $X \leq_{\text{st}} Y$ if, and only if, any one of the following equivalent conditions holds:*

- (i) $N(Z, G) \leq_{\text{st}} N(Z, F)$ for all block replacement schedules Z .
- (ii) $N_m(Z, G) \leq_{\text{st}} N_m(Z, F)$ for all block replacement schedules Z .

Once again, it is worthwhile to mention that Shaked and Szekli [17] obtained a version of Theorem 14 in which under stronger

conditions on X and Y , one obtains stronger conclusions.

As mentioned in the beginning of this section, another extension of the block replacement policy $N(Z)$ is to consider that any time that a unit is replaced, it is replaced by a unit that is not identically distributed as the failed one. Thus, instead of having just one random variable X , we have a sequence of random lifetimes $X_1, X_2, \dots, X_n, \dots$. The sequence of random variables $X_1, X_2, \dots, X_n, \dots$ is said to be NBU [NWU] in sequence if for any $t \geq 0$ and any nonnegative integer n we have

$$[X_n - t | X_n > t] \leq_{\text{st}} [\geq_{\text{st}}] X_{n+1}.$$

For this case, Langberg [21] provided some results similar to the previous ones; we do not give the details here.

COST ANALYSIS

A topic of interest involving block replacement policies is the determination of the optimal time T . In this case, the problem is to determine the expected long-run cost per unit time and then find the value T that minimizes this quantity. For more information on this topic, the reader is directed to Ref. 22 (see also **Optimal Replacement and Inspection Policies**). Here we just give the expected long run cost for block replacement policy under a usual replacement and under a minimal repair.

In order to present the problem, we fix some notation: we will denote by c_f , the cost of replacement of a failed unit and by c_b , the cost of a planned replacement at times $T, 2T, \dots$. In this case, the expected long run cost per unit is

$$\frac{c_f M(T) + c_b}{T},$$

where $M(t)$ is the renewal function.

If instead of the usual replacement policy, we consider a minimal repair for failed units, and the cost of a minimal repair is denoted by c_m , then expected long run cost per unit is

given by

$$\frac{c_m \int_0^T r(u) du + c_b}{T},$$

where r is the failure rate function of X .

Some further analysis can be found in Refs [23–25], and more recently, in Ref. 26 and the references therein.

BRANCH AND CUT

JOHN E. MITCHELL
Department of Mathematical Sciences,
Rensselaer Polytechnic Institute,
Troy, New York

Combinatorial optimization problems can often be formulated as mixed integer linear programming problems, as discussed in the article titled **Formulating Good MILP Models** in this encyclopedia. They can then be solved using *branch-and-cut*, which is an exact algorithm combining branch-and-bound (see **Branch-and-Bound Algorithms** and cutting planes (see the section titled “Cutting Planes”, in the encyclopedia and its articles). The basic idea is to take a linear programming relaxation of the problem, solve the relaxation, and then either improve the relaxation by adding additional valid constraints or split the problem into two or more subproblems and repeat the process.

Gomory first proposed strengthening linear programming relaxations of integer programming problems by incorporating extra constraints (or *cutting planes*) in the 1950s [1]. These cutting planes are derived from the optimal simplex tableau, so they are broadly applicable. However, they fell into disfavor for many years because they seemed to get stuck and run out of power. The cuts are now used in more sophisticated ways and are incorporated into the major commercial packages for integer programming. These packages also include several other families of general cutting planes. General cutting planes are discussed in the sections titled “General Cutting Planes” and “Cutting Planes” in this encyclopedia.

Land and Doig [2] proposed a branch-and-bound approach in 1960. In branch-and-bound, the linear programming relaxation of the integer program is solved. If the solution is fractional, then the problem is split into two subproblems and the process is repeated, creating a tree of subproblems. The value

of the linear programming relaxation gives a lower bound on the optimal value of the integer program at the corresponding node of the tree, for a minimization problem. If this lower bound is greater than the value of a known feasible solution, then the node can be pruned, which greatly reduces the total size of the tree. Branch-and-bound became more popular than cutting plane methods for many years, because of the computational difficulties with the latter.

Interest in cutting planes resurfaced in the 1980s. Crowder *et al.* [3] showed the strength of general cuts obtained by regarding a single row of an integer program as a knapsack problem. In addition, the polyhedral theory of many classes of problems was derived, and this led to problem-specific cutting planes that were very successful, leading to great speed-ups in computational time when compared to using branch-and-bound. For many classes of problems (e.g., the traveling salesman problem), an initial integer programming formulation contains a large number of constraints, possibly even an exponential number. In such a situation, it is not computationally attractive to explicitly include all of these constraints in the LP relaxation, and they can be added selectively as cutting planes. Problem-specific cutting planes are the subject of the section titled “Problem Specific Cutting Planes” of this article.

In theory, pure cutting plane methods can be used to solve integer programs, without the need to employ branching. In practice, cutting plane methods appear to tail-off, and so it becomes faster to combine together the two approaches. Initially, cutting planes were employed only at the root node of the tree, in an approach now called cut-and-branch. Examples include Ref. 3 as well as work on the traveling salesman problem [4]. The set of cuts generated at the root node is not exhaustive, so it is possible that the subsequent branch-and-bound approach leads to an integer solution that is not actually feasible in the integer program. In such a situation, it

is then necessary to add additional cuts and restart the process.

Later in the 1980s, cutting planes were employed throughout the tree. The best known of these results is for the traveling salesman problem, starting with the work of Padberg and Rinaldi [5]; an excellent discussion of this problem is contained in the book by Applegate *et al.* [6]. Other notable early work includes the research of Grötschel *et al.* on the linear ordering problem [7] and on the maximum cut problem [8]. In the 1990s, it was discovered that the general cutting planes can actually be very effective in branch-and-cut approaches to integer programming problems, thanks to the work of Balas *et al.* [9,10]. The integration of cutting planes with branch-and-bound is discussed in more detail in the section titled “The Branch-and-Cut Algorithm” of this article.

Refinements and extensions are discussed in the section titled “Refinements and Extensions.” For example, it is possible to generalize the branch-and-cut approach to solve mixed integer nonlinear programming problems and even nonlinear programs without integrality constraints. Also in this section, we consider exploitation of parallel computational hardware. In addition to parallel computers, it is common for problems to be solved on clusters of computers (including cloud computers) or on the multicore processors, now frequent in desktop and even in laptop computers. Branch-and-cut algorithms can be parallelized by solving different nodes of the tree on different processors.

The Lanchester Prize winning book by Nemhauser and Wolsey [11] contains an excellent discussion of polyhedral theory, integer programming, and branch-and-cut. Other very good and relevant books are those by Wolsey [12] and Lee [13]. The three-volume text by Schrijver [14] is also an excellent reference. Various surveys of branch-and-cut have appeared over the years, including Refs 15–18. The aforementioned text on the traveling salesman problem by Applegate *et al.* [6] provides a very accessible development of integer programming, including branch-and-cut.

GENERAL CUTTING PLANES

Our standard form integer programming problem is the following:

$$\begin{array}{ll} \min & c^T x \\ \text{subject to} & Ax \geq b \\ & x \geq 0 \\ & x_i \text{ integer } \forall i \in I, \end{array} \quad (\text{ILP})$$

where x and c are n -vectors, b is an m -vector, A is an $m \times n$ matrix, and I is a subset of the indices $\{1, \dots, n\}$. Any upper bound constraints on the variables are included in the inequality constraints $Ax \geq b$. The optimal value of (ILP) is denoted by z^* . Any feasible solution $\bar{x}$ to (ILP) provides an upper bound $c^T \bar{x}$ on the optimal value z^* of the problem. A lower bound can be obtained by solving a relaxation of (ILP). In this article, we are concerned with linear programming (LP) relaxations, which are obtained by relaxing the integrality restriction.

The lower bound provided by the LP relaxation can be improved by tightening up the relaxation through the addition of valid linear constraints. Typically, these constraints are satisfied by all feasible solutions to (ILP) but violated by the optimal solution to the LP relaxation. The LP relaxation can be solved again after the addition of the constraints, and the process is repeated.

Cutting planes are discussed in detail in the section titled “Cutting Planes” in this encyclopedia, and its articles. In this section, we summarize some of the cutting planes that have been used to solve general integer programming problems, and which are now included in commercial integer programming packages (see Bixby and Rothberg [19] and Ashford [20]).

Gomory cuts are derived from a row of the optimal simplex tableau for the LP relaxation [21]. These were generalized by Chvátal [22], giving Chvátal–Gomory cuts, which can be derived from any nonnegative linear combination of the linear constraints of (ILP). For simplicity, we consider the case where all the variables are required to be integer. In particular, if $u \in \mathbf{R}^m$ is nonnegative then the constraint

$$u^T Ax \geq u^T b$$

is valid for the LP relaxation of (ILP). Since $x \geq 0$, this constraint can be weakened to

$$\lceil u^T A \rceil x \geq u^T b,$$

where $\lceil u^T A \rceil$ is the n -dimensional row vector obtained by rounding up each entry of the row vector $u^T A$. Since each entry of x is non-negative, the left-hand side of this inequality must be integral for any feasible solution to (ILP). Hence, we can round up the right hand side to obtain the valid constraint

$$\lceil u^T A \rceil x \geq \lceil u^T b \rceil,$$

a Chvátal–Gomory cutting plane. Chvátal showed that any valid inequality for (ILP) can be obtained by repeatedly applying this rounding procedure [22].

Gomory cutting planes fell out of favor for many years, but computational results in the 1990s [10,23] showed that they could be very helpful. According to Bixby and Rothberg [19], they are the most useful of the general cutting planes. Fischetti and Lodi [24] showed that just one round of generating every possible inequality from the original constraints $Ax \geq b$ can give a very good approximation to the convex hull of the set of feasible solutions. Letchford [25] described a method for generating deep Chvátal–Gomory cutting planes. One of the problems with Gomory cutting planes is that eventually dual degeneracy is encountered, which can lead to a basis matrix with a large condition number if care is not taken in the generation of the cuts. Zanette *et al.* [26] demonstrated that employing lexicographic cut generation rules can lead to a set of Gomory cutting planes that interact well with one another and allow a pure cutting plane method to work effectively; see also the related paper in Ref. 27. Gomory cutting planes can also be derived for mixed integer programs; see Marchand and Wolsey [28] for some computational results. Chvátal–Gomory cutting planes are considered in far more detail in the article titled **Gomory Cuts** in this encyclopedia.

Cover inequalities are inequalities that are valid for knapsack problems. Crowder *et al.* [3] considered each row of an integer

program as a separate knapsack problem, and then generated cover inequalities for the individual rows. They showed that this powerful technique could be employed in a cut-and-branch algorithm to solve general integer programming problems. Their approach has been considerably refined in recent years, becoming a standard part of branch-and-cut implementations. These inequalities are discussed in detail in the article titled **Cover Inequalities** in this encyclopedia.

The theory of disjunctive inequalities [29] gives a methodology for generating general cutting planes that can be powerful on certain hard integer programs [9,30]. The theory was originally developed for binary variables and has been extended. Given a binary variable x_i , the process is to find the convex hull of two sets: the set of feasible points in the LP relaxation with $x_i = 0$, and the set of feasible points in the LP relaxation with $x_i = 1$. The process is then iterated over all the binary variables. The theory gives a method to systematically construct the convex hull of the set of feasible solutions to an integer program. Generation of a cut may require solution of a linear program, so in practice this method is used selectively. There are methods for generating disjunctive cuts using the optimal simplex tableau for the relaxation; see Balas and Perregaard [31,32]. For more information, see the articles titled **Lift-and-Project Inequalities** and **Disjunctive Programming** in this encyclopedia.

Recently, there has been interest in deriving cuts using two rows of the simplex tableau, which potentially could be stronger than cuts derived from just a single row. These methods use ideas from lattice theory and group theory. For more details, see Andersen *et al.* [33] and also the survey article by Dey and Tramontani [34].

Computational experience with different classes of general cutting planes is detailed by Bixby and Rothberg [19]. One point the authors make is that different families of cutting planes can interact with each other, so the benefit of using all of several different families of cuts is not necessarily equal to the product of the benefits of using each family individually.

PROBLEM-SPECIFIC CUTTING PLANES

Many combinatorial optimization problems can only be expressed as integer linear programming problems with an exponential number of constraints. For example, a standard formulation of the traveling salesman problem uses degree constraints to ensure each city is visited exactly once. It also requires the inclusion of subtour elimination constraints to ensure that any integral solution corresponds to a tour that connects all the cities, and the number of subtour elimination constraints is exponential in the number of cities. Thus, it is impractical to include all of these constraints in the integer programming formulation, and they should be added as cutting planes. The first demonstration of the strength of this cutting plane approach was by Dantzig *et al.* [35], who showed that a problem with 42 cities could be solved to optimality by adding just a limited number of subtour elimination constraints, and some other cutting planes. Cutting plane methods for the traveling salesman problem were revisited in the 1980s [36,37], and subsequently the work of Applegate *et al.* [6] has realized an algorithm that can find provably optimal solutions to problems with as many as 85,900 cities. Their code Concorde is freely available.

The convex hull of the set of feasible integer solutions to a combinatorial optimization problem is a polyhedron. (See **Basic Polyhedral Theory** for more details.) If a linear programming description of this polyhedron is known, then the problem can be solved effectively. However, the number of facets of the polyhedron is large (often exponential) for interesting combinatorial optimization problems. Thus, it is necessary to add the constraints selectively. The strongest cutting planes correspond to facets, and families of facets have been determined for many different problems. For example, the subtour elimination constraints mentioned earlier define facets.

Other problems, for which cutting plane methods have been developed, include the linear ordering problems [7,38] with triangle inequalities and other classes of facet defining inequalities, the maxcut problem

[8,39–44] with cycle-odd subset inequalities, matching problems [45,46], clique and coloring problems [47,48], fixed charge network flow problems [49], vehicle routing problems [50–52], and facility location problems [53].

Knowledge of a strong family of cutting planes is only useful in practice if effective separation routines are also developed, which can find violated constraints in the family efficiently. These separation routines can be simple or involved, even for the same class of constraints. For example, cycle-odd subset inequalities for maxcut problems can be checked by enumeration for all short cycles, but in order to guarantee that any violated inequality can be found it is necessary to use a max-flow algorithm for a graph derived from the original one [41]. Violated subtour elimination constraints for the traveling salesman problem can be found by searching for connected components in the solution to the LP relaxation, but this may not find all violated constraints, so more expensive routines have also been developed [6].

Let X be a feasibility integer program and let x be a point. The *separation problem* for X and x is to find a cutting plane that separates x from the convex hull of X , or determine that x is in this convex hull. If the separation problem for any point x can be solved in time no greater than $g(X)$, then problem X itself can be solved in time polynomial in $g(X)$ using the ellipsoid algorithm. This observation can be generalized as the equivalence of separation and optimization problems [54]. It follows that for an NP-Complete problem, it will not be possible to find a cutting plane for each point not in the convex hull in polynomial time (unless $P = NP$).

THE BRANCH-AND-CUT ALGORITHM

A branch-and-cut algorithm is outlined in Algorithm 1. The set of active nodes in the branch-and-cut tree is denoted by L . The value of the best known feasible point for (ILP) is stored as $\bar{z}$, and provides an upper bound on the optimal value of the integer program. This point is called the *incumbent solution*. We use $\underline{z}_l$ to denote a lower bound on the optimal value of the current subproblem l , under consideration. This lower bound

is initialized to the value of the parent node, and is then updated to the value of the LP relaxation of the subproblem.

Algorithm 1. A general branch-and-cut algorithm.

1. *Initialization:* Denote the initial integer programming problem by ILP^0 and define the set of active nodes to be $L = \{ILP^0\}$. Let $\bar{z} = +\infty$. Set $z_l = -\infty$ for the initial problem $l \in L$.
2. *Termination:* If $L = \emptyset$, then STOP. If $\bar{z} = \infty$ then (ILP) is infeasible; else, the solution x^* which yielded the incumbent objective value $\bar{z}$ in Step 7(b) or Step 5 is optimal.
3. *Problem selection:* Select and delete a problem ILP^l from L .
4. *Relaxation:* Solve the LP relaxation of ILP^l . If the relaxation is infeasible, set $z_l = +\infty$ and go to Step 7. If the relaxation is unbounded set $z_l = -\infty$. If the relaxation has a finite optimal value let x^{LR} be an optimal solution and set $z_l = c^T x^{LR}$.
5. *Heuristic Rounding:* If x^{LR} is not integral, and if desired, use a rounding approach or a heuristic approach to construct a feasible integral solution x^{IH} . Update $\bar{z} = \min\{c^T x^{IH}, \bar{z}\}$.
6. *Add cutting planes:* If desired, search for cutting planes that are violated by x^{LR} ; if any are found, add them to the relaxation and return to Step 4.
7. *Fathoming and Pruning:*
 - a. *Fathom by bounds or infeasibility:* If $z_l \geq \bar{z}$ go to Step 2.
 - b. *Fathom by integrality:* If $z_l < \bar{z}$ and x^{LR} is integral feasible, update $\bar{z} = z_l$, delete from L all problems with $z_l \geq \bar{z}$, and go to Step 2.
8. *Partitioning:* Let $\{S^{lj}\}_{j=1,\dots,k}$ be a partition of the constraint set S^l of problem ILP^l . Add problems $\{ILP^{lj}\}_{j=1,\dots,k}$ to L , where ILP^{lj} is ILP^l with feasible region restricted to S^{lj} , and set $z_{lj} = z_l$ for $j = 1, \dots, k$. Return to Step 2.

Without the inclusion of Step 6, this becomes a branch-and-bound algorithm.

A crucial point with branch-and-bound is that a subproblem l can be discarded once $z_l \geq \bar{z}$, since it is then known that no feasible solution to the subproblem can be better than the incumbent solution. The other method for fathoming in Step 7 is when the optimal solution to the LP relaxation of the subproblem is feasible in the integer program, since this LP solution then solves the subproblem. The reader is referred to the article titled **Branch-and-Bound Algorithms** in this encyclopedia for far more discussion of branch-and-bound, including preprocessing, options for branching, and reduced cost fixing and its exploitation.

The particular procedure employed in Step 5 can be a generic rounding procedure, or it can be a rounding procedure modified to exploit the particular structure of the problem, or it can be a heuristic initiated either at the point x^{LR} or at a rounded version of this point.

The Step 6 decision of when to add cutting planes and when to branch can probably only be resolved through computational experimentation. The conclusion is dependent on the particular class of integer program and on the types of cutting planes considered. Different types of cutting planes interact with each other, so care is needed in experimentation in order to determine reproducible benefits.

Cutting planes generated at one node of the tree may not be valid at another node. One option is to treat the cuts as local, and only use them for descendants of the node where they are generated. The disadvantage of this approach is that it becomes necessary to store several different sets of constraints, for different parts of the tree. Alternatively, the constraints can be modified to make them valid throughout the tree, using a process called *lifting*. In lifting, the value of the slack in the constraint is checked in the remainder of the tree, either by solving integer programs to get strong liftings or LP relaxations to get somewhat weaker lifted inequalities. Lifting is a general process for strengthening and modifying constraints and is discussed in the article titled **Lifting Techniques for Mixed Integer Programming** in this encyclopedia.

One important aspect of a general integer programming code is preprocessing. One aspect of preprocessing is to tighten bounds on the variables and constraints by logical arguments and possibly solving LPs. This may lead to variable fixing or constraint elimination, and can have a dramatic impact on runtime (an average improvement of a factor of 10 for the problems considered in Ref. 19). Far more about preprocessing can be found in the article titled ***Branch-and-Bound Algorithms*** in this encyclopedia.

REFINEMENTS AND EXTENSIONS

Computational implementations of branch-and-cut are now very sophisticated and include many ideas from the research literature of the last 30 years. Commercial codes include CPLEX and GuRoBi [19], and XPRESS-MP [20]. Recent high-quality free software includes the COIN-OR branch-and-cut package Cbc [55], and the packages ABACuS [56] and MINTO [57]. In this section, we consider some possible enhancements to current integer programming solvers.

Before discussing enhancements, we note that the computing environment is becoming ever more parallel. There have been sophisticated parallel computers for many years, and these have become more widespread, with local machines with at least 100 processors available to many users. In addition, there are now clusters of homogeneous or heterogeneous processors linked together using software, there is the availability of cloud computing, and multicore processors are common in desktop and even in laptop computers. This is an environment that must be exploited for a branch-and-cut implementation to remain competitive. Fortunately, the branching aspect of these algorithms leads to a natural way to parallelize: different subproblems in the tree are solved in different processors of the machine. Load balancing requires careful consideration, but in principle branch-and-cut algorithms should flourish in a world of parallel computers. For more concrete discussion of these issues, see Ref. 55.

A standard model for the traveling salesman problem is to use one variable for

each edge, so if the graph has n vertices then there are $O(n^2)$ variables. Based just on the objective function coefficients, it is clear that the great majority of the variables can be (at least temporarily) fixed at zero. Thus, we can work with integer and linear programs where the number of variables is $O(n)$. Before fathoming any node of the tree, the eliminated edges can be checked using reduced costs, to see if they would have been helpful. This pricing step may lead to the introduction of variables, and the resulting algorithm is a form of branch-and-price-and-cut. For more on algorithms of this type, see the article titled ***Branch-Price-and-Cut Algorithms*** in this encyclopedia.

Many integer programming formulations possess a natural symmetry. For example, when scheduling jobs on several identical machines, the important decision is determining which set of jobs go together on a particular machine and then sequencing those jobs. Which machine performs which particular set of jobs does not matter. This poses difficulties for a standard branch-and-cut approach, because many variables have to be fixed in the branching tree before the symmetry is broken. There has been research on methods for breaking symmetry, using ideas from group theory and algebra [58,59]. See the article titled ***Symmetry Handling in Mixed-Integer Programming*** in this encyclopedia for more information.

Classically, cutting planes are satisfied by all feasible solutions. Cuts could potentially be strengthened by requiring only that all *optimal* solutions satisfy them. A similar possibility is noted in dual stabilization of column generation algorithms; see Ref. 60 for example.

Fischetti *et al.* [61] note that it is possible to use sophisticated mixed integer programming techniques within a branch-and-cut solver. For example, the separation problems for some classes of cutting planes are themselves hard integer programs and so it is beneficial to use whatever MIP techniques are available in order to find strong cutting planes; see Ref. 47 for example. Construction of an initial feasible solution can also be performed by using integer programming techniques such as local branching [62].

It is superior to use interior point methods instead of the simplex method for some problems, at least in certain parts of the branch-and-cut process. Interior point methods have two potential advantages: first, cuts are generated from a more central solution, which leads to deeper cuts; secondly, interior point methods can solve large problems more quickly than simplex, and when many cuts are added at once the warm-start benefit enjoyed by simplex is no longer so advantageous. See Ref. 63 for a survey, and Ref. 44–46 for computational results. Branch-and-cut can also be integrated with convex relaxations of the integer program, such as semidefinite relaxations [63,65–67].

Branch-and-cut algorithms have also been developed for mixed integer nonlinear programming problems. The cuts used in these approaches are typically disjunctive cuts. See Bonami *et al.* [68], which describes several different possible branch-and-cut approaches.

Branch-and-cut can even be used for problems without integrality restrictions. For example, Tawarmalani and Sahinidis [69,70] describe an approach for global optimization of general nonlinear programs, and Vandenbussche and Nemhauser [71] show how branch-and-cut can be used to solve a nonconvex quadratic program by exploiting the optimality conditions.

CONCLUSIONS

The performance of branch-and-bound methods for integer programming has been dramatically improved by the inclusion of cutting planes, leading to branch-and-cut. The resulting exact methods have been successfully implemented in powerful general purpose solvers for mixed integer programs, and they are the method of choice for solving hard integer programs to optimality. The software has improved by several orders of magnitude in the last few years. Branch-and-cut solvers have also been developed for specific problems such as the traveling salesman problem, with such a code currently able to solve larger problems to optimality than any other approach. Branch-and-cut methods

are still the subject of active research, with various ideas showing promise. The methods have also been extended to solve mixed integer nonlinear programs, and other classes of optimization problems.

BRANCH-AND-BOUND ALGORITHMS

KIAVASH KIANFAR
Department of Industrial and Systems
Engineering, Texas A&M University,
College Station, Texas

For most discrete optimization problems, complete (or explicit) enumeration of solution space to find the optimal solution is out of question because even for small problem sizes the number of solution points in the feasible region is extremely large (e.g., even if a single point can be enumerated in 10^{-10} s, enumerating all points in a relatively small problem with only 75 binary variables will take about 120,000 years!). *Branch-and-bound* is a general purpose approach to *implicitly* enumerate the feasible region and was first introduced by Land and Doig [1] for solving integer programming problems. It works based on a few simple principles to avoid enumerating every solution point explicitly.

Although branch-and-bound is often discussed in the context of integer programming, it is actually a general approach that can also be applied to solve many combinatorial optimization problems even when they are not formulated as integer programs. For example, there are efficient branch-and-bound algorithms specifically designed for job shop scheduling or quadratic assignment problems, which are based on the combinatorial properties of these problems and do not use their integer programming formulations. Nevertheless, it is true that almost all integer programming solvers use branch-and-bound to solve IP problems and, therefore, application of branch-and-bound in the context of IP is of special importance. In this article we present the main concepts of branch-and-bound in a general setting and then discuss some problem-specific details in the context of integer programming. Many of these details can be extended to more general settings other than IP depending on the problem that is being solved.

BRANCH-AND-BOUND BASIC IDEAS

In this section we explain the main concepts of branch-and-bound as a general discrete optimization approach. Many of branch-and-bound concepts discussed here are based on Nemhauser and Wolsey [2] and Wolsey [3] the reader can refer to these resources for further reading. Consider a general combinatorial optimization problem like

$$z = \max \{f(x) : x \in S\}.$$

Branch-and-bound is a divide and conquer strategy, which decomposes the problem to subproblems over a *tree* structure, which is referred to as *branch-and-bound tree*. The decomposition works based on a simple idea: If S is decomposed into S^1 and S^2 such that $S = S^1 \cup S^2$, and we define subproblems $z^k = \max\{f(x) : x \in S^k\}$ for $k = 1, 2$, then $z = \max_k z^k$. Each subproblem represents a *node* on the tree. Fig. 1 shows a schematic of a branch-and-bound tree. The main problem with feasible region S (for simplicity we call it problem S) is at the *root node*, and is then divided into two subproblems (with feasible regions) S^1 and S^2 , where we have $S^1 \cup S^2 = S$. The process of dividing a node subproblem into smaller subproblems is called *branching* and subproblems S^1 and S^2 are called *branches* created at node S . In Fig. 1 subproblem S^1 is further branched into smaller subproblems and so on. The branching does not necessarily have to be two-way, and multiway branching is also possible.

Observe that branching indefinitely will only result in explicit enumeration of the feasible region of S . Therefore to avoid explicit enumeration, in branch-and-bound whenever possible a branch is pruned (or fathomed), meaning that its subproblem is not divided anymore. In other words, the feasible region of the node subproblem is implicitly enumerated without branching any deeper. But when can we prune a branch? The main idea is to use bounds on the objective value of subproblems intelligently to prune branches. That is why the method is called *branch-and-bound*.

Figure 1. Subproblems in a branch-and-bound tree.

Fig. 2 shows the flow chart of the branch-and-bound algorithm in a general context. For a maximization problem, a lower bound $\underline{z}$ is updated throughout the algorithm and is used in pruning the nodes. The updating of the lower bound is normally triggered by finding an optimal solution with a better objective value at a node subproblem. Clearly, an optimal solution at a node problem gives a lower bound on z . Additionally, the branch-and-bound algorithm must have a mechanism to calculate an upper bound for the objective value of a node subproblem. For example, in IP solving the linear programming (LP) relaxation of the subproblem gives an upper bound on the IP objective value. As observed in Fig. 2, in general, a node is pruned if one of the following cases happens:

Pruning by infeasibility. If the feasible region of a node subproblem is empty, the node is naturally pruned.

Pruning by bound. If the upper bound calculated for a node subproblem is not greater than the lower bound on z , that is, $\bar{z}^i \leq \underline{z}$, then the node is pruned because there is no point in searching the feasible region of that node when we know that the best objective value we can obtain is not better than a solution we already know.

Pruning by optimality. When it is possible to find the optimal solution to a node subproblem S^i , then the node is

pruned and its solution is stored as the incumbent if its objective value is better than the best we know so far. The lower bound $\underline{z}$ is also updated in this case.

If a node cannot be pruned based on any of the above conditions then new branches are created to decompose the node subproblem into smaller problems. The algorithm stops when all nodes are pruned, that is, there is no active node remaining. The optimal solution will be the incumbent solution with objective value $\underline{z}$. The finiteness of the number of steps in a branch-and-bound algorithm has been theoretically studied and proved within a general formulation in works such as Refs 4 and 5.

This provides a complete high level view of branch-and-bound. In a more technical level there are many detailed questions that must be addressed in implementing the algorithm. The answers to many of these questions depend upon the particular problem being solved. Some of these questions are as follows [3]:

- How should the upper bounds be calculated?
- What is the appropriate balance between the time spent to find an upper bound and the strength of the upper bound?
- How should we do the branching, that is, how should a node subproblem be decomposed into smaller problems?
- How many branches should be created at each branching? Two or more?
- Should the branching rule be an a priori rule or should it adapt as the algorithm proceeds?
- How should we choose the next active node to consider?

As mentioned, almost all solvers for IP problems use branch-and-bound. In the next section, we discuss the LP-based branch-and-bound algorithm for solving an IP problem specifically and address the questions above in the context of solving the IP problem.

Figure 2. General branch-and-bound algorithm.

LP-BASED BRANCH-AND-BOUND TO SOLVE INTEGER PROGRAMMING PROBLEMS

Consider an integer programming problem like

$$z = \max \{cx : x \in S\},$$

where $S = \{x : x \in Z^n \cap P\}$ and P is a polyhedron. As before we refer to this problem as problem S . For simplicity we talk about pure integer programming problems but what follows can be easily extended to mixed integer programming problems too. Figure 3 shows the flow chart of the branch-and-bound algorithm for solving the IP problem S . This flow chart is a special case of the general flow chart of Fig. 2 customized in order to solve the IP problem.

Illustrative Example. Consider the IP problem S :

$$\begin{aligned} \max z &= 3x_1 + 2x_2 \\ 3x_1 + 4x_2 &\leq 12 \\ 2x_1 + x_2 &\leq 5 \\ x_1, x_2 &\geq 0 \text{ and integer.} \end{aligned}$$

The branch-and-bound tree for solving this problem is shown in Fig. 4.

Observe in Fig. 4 how the calculation of bound in the right branch helps us to prune the left branch and therefore saves us the effort of further enumerating the solutions in that branch.

Now let us address in more detail some of the questions we posed at the end of the section titled “Branch and Bound Basic

Figure 3. Branch-and-bound flow chart for solving an IP problem.

Figure 4. Branch-and-bound tree for the example problem.

Ideas" with respect to branch-and-bound for solving the IP problem.

Bounding

Solving the LP relaxation of any IP subproblem S^i gives an upper bound on its objective value. This is the bound that is most commonly used in practice. The LP is usually solved using simplex-based algorithms. On very large models interior point methods may be best for solution of the first LP [3]. A desirable feature of LP relaxation with simplex is that an optimal or near-optimal basis of the problem can be stored so that the LP relaxation in subsequent nodes can be reoptimized rapidly.

Branching

An important question is how to branch, meaning how to split a subproblem into smaller subproblems. Here we review the most common methods.

Single Variable Branching. The simplest idea to split the feasible region of a subproblem S^i with formulation P^i is to pick an integer variable with fractional value in the LP relaxation optimal solution, say x_j with value $\bar{x}_j$, and create branches by adding simple linear constraints to formulation P^i as follows:

$$\begin{aligned} S^{i1} &= S^i \cap \{x : x_j \leq \lfloor \bar{x}_j \rfloor\} \\ S^{i2} &= S^i \cap \{x : x_j \geq \lceil \bar{x}_j \rceil\}. \end{aligned}$$

S^{i1} is usually referred to as the *left (down) branch* and S^{i2} is referred to as the *right (up) branch*. This is a desirable choice because clearly we have $S^i = S^{i1} \cup S^{i2}$ and $S^{i1} \cap S^{i2} = \emptyset$, and furthermore, the current LP solution is not feasible for any of S^{i1} and S^{i2} so in the absence of multiple optima for LP the upper bound would strictly decrease in each of these branches. This branching scheme was first introduced in Ref. 6.

A generalization of the above branching scheme is using branches such as $S^{i1} = S^i \cap \{x : dx \leq d_0\}$ and $S^{i2} = S^i \cap \{x : dx \geq d_0 + 1\}$ in which d and d_0 are integer. However, in practice, only the simplest form which is the

above single variable branching is used in all solvers.

With the single variable branching strategy, an important question is which variable should be chosen out of all variables with fractional value? A recent comprehensive study on this issue is done in Ref. 7; also see Refs 2, 3, 8, 9. An old and common rule is the *most fractional variable*. If C is the set of all integer variables with fractional LP relaxation value then the chosen variable is

$$\operatorname{argmax}_{j \in C} \min \{f_j, 1 - f_j\},$$

where $f_j = \bar{x}_j - \lfloor \bar{x}_j \rfloor$. When branching is based on this rule, it is recommended that the $x_j \leq \lfloor \bar{x}_j \rfloor$ branch is considered first only if $f_j \leq 1 - f_j$. Otherwise the $x_j \geq \lceil \bar{x}_j \rceil$ should be selected first. Example in Fig. 4 obeys this rule. Accordingly the most fractional variable, that is, x_1 , is chosen as the branching variable and then the right branch is selected after the root node because $f_1 = x_1 - \lfloor x_1 \rfloor = 0.6 > 0.4 = 1 - (x_1 - \lfloor x_1 \rfloor) = 1 - f_1$.

The most fractional rule is simple to implement but in Ref. 7, it is shown computationally that this rule is not better than just any random variable selection rule. More effective strategies have been proposed and studied over the years, which are more sophisticated. The method of *pseudocost branching* goes back to [10] and works based on calculating a pseudocost by keeping a history of success (change in LP relaxation value) of the left and right branching performed on each variable. The branching variable with the highest pseudocost is chosen each time. Different functions have been proposed for the pseudocost such as maximum of sum of left and right *degradations* (decrease in upper bound) [11], maximum of the smaller of the left and right degradations [10]; also see Ref. 8.

Strong branching [8,12] is in a sense an extreme effort to find the best branching variable. In its full version, at any node one tentatively branches on each candidate variable with fractional value and solves the LP relaxation for right and left branches for each variable either to optimality or for a specified number of dual simplex iterations. The degradation in bound for left and right

branches are calculated and the variable is picked on the basis of the function of these degradations [3,8]. In addition to a number of dual simplex method iterations, the computational effort of strong branching can also be limited by defining a much smaller set of candidate branching variables.

An effective variable selection strategy was proposed in Ref. 7 called *reliability branching*. This method integrates strong and pseudocost branching. A threshold is defined on the number of previous branchings involving a variable. Below this threshold the pseudocost is considered unreliable and strong branching is used but above the threshold the pseudocost method is used.

We also note that many solvers provide the user with the option of assigning *user-specified priorities* to the integer variables. When branching, the solver picks the variable with a fractional value that has the highest assigned priority. This is especially useful when the user has some insight regarding the importance of variables based on what they represent in the application underlying the model [3].

GUB Branching. Many IP models contain the so-called *Generalized Upper Bound* (GUB) or *Special Ordered Set* (SOS) constraint of the form

$$\sum_{j=1}^n x_j = 1$$

with $x_j \in \{0, 1\}$ for $j = 1, \dots, n$. If the single variable branching on one of the variables $x_j, j = 1, \dots, n$, is performed then the two branches will be $S^{i1} = S^i \cap \{x : x_j = 0\}$ and $S^{i2} = S^i \cap \{x : x_j = 1\}$. Because of the GUB constraint, $\{x : x_j = 0\}$ will leave $n - 1$ possibilities $\{x : x_i = 1\}_{i \neq j}$ while $\{x : x_j = 1\}$ leaves only one possibility. So S^{i1} is usually much larger than S^{i2} and the tree is unbalanced. A more balanced split is desired and GUB branching proposed in Ref. 13 is a way to get a balanced tree which works as follows: The user provides a special order of variables in the GUB set, say $j_1, \dots, j_n$. Then the two

branches will be as follows:

$$S^{i1} = S^i \cap \{x : x_{j_i} = 0, i = 1, \dots, r\}$$

$$S^{i2} = S^i \cap \{x : x_{j_i} = 0, i = r + 1, \dots, n\},$$

where $r = \min \{t : \sum_{i=1}^t \bar{x}_{j_i} \geq \frac{1}{2}\}$. The number of nodes is usually significantly reduced with this branching scheme compared to the single variable branching.

Node Selection

Having a list of active (unpruned) nodes, the question is which node should be examined next. There are two categories of rules for this purpose: *static rules* that determine in advance the order of node selection and *adaptive rules* which use the information about the status of active nodes to choose a node. For a complete review of different node selection strategies see Ref. 8. Among static rules the *depth-first* and the *best-bound* (or *best-first*) are the two well-known extremes.

Depth-First Node Selection. Depth-first rule also known as *last in, first out* (LIFO) is as follows: if the current node is not pruned the next node is one of its children; and if it is pruned the next node is found by *backtracking* which means the next node is the child of the first node on the path from the current node to the root node with an unconsidered child node. Obviously, this is a completely a priori rule if a rule is specified to select between left and right children of a node. This rule has known advantages:

1. For pruning the tree a good lower bound is needed. The depth-first method descends quickly in the tree to find a first feasible solution which gives a lower bound that hopefully causes the pruning of many future nodes.
2. The depth-first method tends to minimize the memory requirements for storing the tree at any given time during the algorithm.
3. Passing from a node to its immediate child has the advantage that the LP relaxation can be easily resolved by adding just an additional constraint.

However, the depth-first search can result in an extremely large search tree. This is the result of the fact that we may need to consider many nodes that would have been fathomed if we had a better lower bound.

Best-Bound Node Selection. In this rule the next node is the active node with the best (largest) upper bound. With this rule one would never branch a node whose upper bound is less than the optimal value. As a result this rule minimizes the number of the nodes considered. However, the memory requirements for this method may become prohibitive if good lower bounds are not found early leading to relatively little pruning. In terms of reoptimizing the LP relaxations this method is also at a disadvantage because one LP problem has little relation to the next one.

Adaptive Node Selection. Adaptive methods make intelligent use of information about the nodes to select the next node. The *estimate-based methods* attempt to select nodes that may lead to improved integer feasible solutions. The *best projection* criterion [14] and the *best estimate* criterion found in Refs 10 and 15 are among these methods.

Many adaptive methods are *two-phase* methods that essentially use a hybrid of depth-first and best-bound searches. At the beginning the depth-first strategy is used to find a feasible solution and then the best-bound method is used [16]. Variations of two-phase methods using estimate-based approaches are also proposed [15,17]. Some other suggested rules use an estimation of the optimal IP solution to avoid considering *superfluous* nodes, that is, the nodes in which $\bar{z}^i < z$. The tree is searched in a depth-first fashion as long as $\bar{z}^i$ is greater than the estimate. After that a different criterion such as best-bound is used [10,11].

EXTENSIONS OF BRANCH-AND-BOUND

In solving integer programming *problems*, pure branch-and-bound is seldom used. In most cases cutting planes are added to the

root problem or the node subproblems to tighten the feasible region of the LP relaxation and hence obtain better bounds faster. A branch-and-bound algorithm in which cutting planes are used is known under the general name of *branch-and-cut* [2,3,18].

In branch-and-cut at any node, after optimizing the LP relaxation, a *separation* problem is solved to find valid inequalities for feasible integer solutions, which are violated by the LP relaxation solution. These valid inequalities are then added to the problem and the problem is reoptimized to improve the LP relaxation bound. Branching happens when no further valid inequalities can be found. Of course the amount of effort spent to find valid inequalities is one of the parameters of the algorithm that should be decided. We refer the reader to the article titled **Branch and Cut** in this encyclopedia for further information.

Another extension of branch-and-bound is *branch-and-price* [2,3,19]. When the number of variables in an integer program is huge, a solution method is using *column generation* within the branch-and-bound framework. More specifically, implicit pricing of nonbasic variables is used to generate new columns or to prove LP optimality at a node of the branch-and-bound tree. Branching happens when no columns price out to enter the basis and the LP solution does not satisfy integrality constraints. We note that if cutting planes are also used in branch-and-price the algorithm is called *branch-cut-price*. We refer the reader to the article titled **Branch-Price-and-Cut Algorithms** in this encyclopedia for further information.

PARALLEL BRANCH-AND-BOUND

The divide and conquer nature of branch-and-bound makes it a suitable framework for attacking huge problems using today's parallel computing capabilities. For a survey of parallel branch-and-bound algorithms refer to Ref. 20. There are three types of parallelism that can be implemented for a branch-and-bound algorithm: Type 1 is parallel execution of operations on generated subproblems, for example, parallel bounding

operations for each subproblem to accelerate execution. Type 2 consists of building the tree in parallel by performing operations on several subproblems simultaneously. Type 3 is building several trees in parallel. In each tree some operation such as branching, bounding or selection is performed differently but the trees share their information and use the best bounds among themselves. For further reading refer to Ref. 20.

BRANCH-PRICE-AND-CUT ALGORITHMS

JACQUES DESROSIERS
HEC Montréal and GERAD,
Montréal, Canada

MARCO E. LÜBBECKE
Chair of Operations Research,
RWTH Aachen University,
Aachen, Germany

Decompositions and reformulations of mixed integer programs are classical approaches to obtaining stronger relaxations and reduce symmetry. These often entail the dynamic addition of variables (columns) and/or constraints (cutting planes) to the model. When the linear relaxation in each node of a branch-and-bound tree is solved by column generation, one speaks of branch-and-price. Optionally, as in standard branch-and-bound, cutting planes can be added in order to strengthen the relaxation, and this is called *branch-price-and-cut*. Now, having understood and familiarized oneself with the three concepts, branch-and-bound (see **Branch-and-Bound Algorithms**), column generation (see **Column Generation**), and cutting planes (see the section titled “Automatic Convexification” in this encyclopedia); one may think that the above explanation is the end of the story. Actually, this understanding is precisely where the story begins. Strengthening the relaxation by means of cutting planes and performing branching on fractional variables both interfere with column generation and may entirely ruin the mentioned advantages of a decomposition when done naively.

In early years, one attempted to circumvent these complications in an *ad hoc* fashion [1] but over time a generic theoretical understanding developed. The state-of-the-art relies on the relation between the original problem and its extended reformulation, as first used in Desrosiers *et al.* [2].

There are very successful applications of branch-and-price in industry (see Desrosiers

and Lübbecke [3], and also the section titled “Vehicle Routing and Scheduling” in this encyclopedia) and also to generic combinatorial optimization problems like bin packing and the cutting stock problem [4], graph coloring [5], machine scheduling [6], the p -median problem [7], the generalized assignment problem [8], and many others. The method today is an indispensable part of the integer programming toolbox.

COLUMN GENERATION

Consider the following *integer master problem*

$$\begin{aligned} \min \quad & \sum_{j \in J} c_j \lambda_j \\ \text{subject to} \quad & \sum_{j \in J} \mathbf{a}_j \lambda_j \leq \mathbf{b} \\ & \lambda \in \mathbb{Z}_+^{|J|}. \end{aligned} \quad (1)$$

In many applications, $|J|$ is huge (but always finite) and we solve the linear relaxation of problem (1), called the *master problem*, by column generation as follows (see **Column Generation**). The *restricted master problem* (RMP) contains only a subset $J' \subseteq J$ of variables, initially possibly none. In each iteration, (i) we obtain λ^* and π^* , the primal and dual optimal solutions to the RMP, respectively. Then, (ii) the following pricing problem (subproblem) is to be solved

$$v := \min_{\mathbf{x} \in X} \{c(\mathbf{x}) - \pi^* a(\mathbf{x})\}, \quad (2)$$

where $c_j = c(\mathbf{x}_j)$ and $\mathbf{a}_j = a(\mathbf{x}_j)$ reflect that each column $j \in J$ is associated with an element $\mathbf{x}_j \in X$ from a domain X over which we can optimize, often a set of combinatorial objects like paths or other subgraphs (so, usually, the $\mathbf{x}_j$ bears much more information than just the column $a(\mathbf{x}_j)$). When $v < 0$ the variable λ_j and its coefficient column $(c_j, \mathbf{a}_j)$ corresponding to a minimizer $\mathbf{x}_j$ are added to the RMP, and the process is

iterated. Otherwise, $v \geq 0$ proves that there is no such improving variable, and the current λ^* is an optimal solution to the master problem.

DECOMPOSITIONS AND REFORMULATIONS

In general, when solving mathematical programs involving integer variables, a *good* model is of utmost importance, refer to Nemhauser and Wolsey [9] for some general considerations (see also the section titled “Models and Algorithms” in this encyclopedia). After all, the whole integer programming machinery is about better describing the convex hull of feasible integer solutions: tighter relaxations from a different modeling choice and cutting planes fulfill this purpose. Also, branch-and-price is motivated by the perspective for better dual bounds and reduced problem symmetry. In the following we describe the groundwork.

Dantzig–Wolfe Decompositions for Integer Programs

The Dantzig–Wolfe decomposition principle in linear programming [10] was devised to exploit sparsity and special structure in linear programs (see also **Dantzig–Wolfe Decomposition**). However, it reveals its true strength only when adapted to integer programs. We assume that optimizing over the mixed integer set $X = \{\mathbf{x} \in \mathbb{Z}_+^n \times \mathbb{Q}_+^q \mid D\mathbf{x} \leq \mathbf{d}\}$ is “relatively easy,” which however, is overshadowed by additional *complicated* constraints, that is,

$$\begin{aligned} \min \quad & \mathbf{c}\mathbf{x} \\ \text{subject to} \quad & A\mathbf{x} \leq \mathbf{b} \\ & \mathbf{x} \in X \end{aligned} \quad (3)$$

is rather hard to solve when the “hidden” structure X is not exploited. The mixed integer program (3) is called the *original* problem in this context and we call $\mathbf{x}$ the *original* variables. As we will see, a decomposition will lead to a master and a pricing problem as above. It was noted already by Geoffrion [11] in the context of Lagrangean relaxation (see also **Lagrangian Optimization for LP**)

that decomposing problem (3) by solving over X as a mixed integer program (and penalizing the violation of $A\mathbf{x} \leq \mathbf{b}$ in the objective function) may yield a stronger dual bound than the standard linear relaxation when the convex hull $\text{conv}(X)$ is not an integral polyhedron. In this article, X is assumed to be a pure integer set, that is, $q = 0$; we only point to the mixed integer generalization when needed.

Convexification. The classical decomposition approach builds on the representation theorems by Minkowski and Weyl [12] and *convexifies* X , hence the name. Each $\mathbf{x} \in X$ can be expressed as a convex combination of finitely many extreme points $\{\mathbf{x}_p\}_{p \in P}$ plus a nonnegative combination of finitely many extreme rays $\{\mathbf{x}_r\}_{r \in R}$ of $\text{conv}(X)$, that is,

$$\begin{aligned} \mathbf{x} &= \sum_{p \in P} \mathbf{x}_p \lambda_p + \sum_{r \in R} \mathbf{x}_r \lambda_r, \\ \sum_{p \in P} \lambda_p &= 1, \quad \lambda \in \mathbb{Q}_+^{|P|+|R|}. \end{aligned} \quad (4)$$

Substituting for $\mathbf{x}$ in the original problem (3) and applying the linear transformations $c_j = \mathbf{c}\mathbf{x}_j$ and $\mathbf{a}_j = A\mathbf{x}_j, j \in P \cup R$ one obtains an *extended formulation* equivalent to problem (3), which is an *integer master problem* as Equation (1)

$$\begin{aligned} \min \quad & \sum_{p \in P} c_p \lambda_p + \sum_{r \in R} c_r \lambda_r \\ \text{subject to} \quad & \sum_{p \in P} \mathbf{a}_p \lambda_p + \sum_{r \in R} \mathbf{a}_r \lambda_r \leq \mathbf{b} \\ & \sum_{p \in P} \lambda_p = 1 \\ & \lambda \geq \mathbf{0} \\ & \mathbf{x} = \sum_{p \in P} \mathbf{x}_p \lambda_p + \sum_{r \in R} \mathbf{x}_r \lambda_r \\ & \mathbf{x} \in \mathbb{Z}_+^n. \end{aligned} \quad (5)$$

The constraints involving only λ variables are called *coupling constraints* and *convexity constraints*, respectively. It is important to note that integrality is still imposed on the original $\mathbf{x}$ variables. Owing to the large

cardinality of $P \cup R$ the LP relaxation of Equation (5) is solved by column generation (see **Column Generation** and the section titled “Column Generation”), where the constraints linking $\mathbf{x}$ and λ variables can be dropped. Thus, only the dual variables π and π_0 remain relevant where π_0 corresponds to the convexity constraint. The pricing problem is the integer program

$$\min \{ \mathbf{c}\mathbf{x} - \pi\mathbf{A}\mathbf{x} - \pi_0 \mid \mathbf{x} \in X \}, \quad (6)$$

for which, ideally, a tailored combinatorial algorithm is available; and if not, we need to solve it with some standard IP solver which may be very time consuming.

Discretization. In contrast to convexification where $\text{conv}(X)$ is reformulated, *discretization* is a reformulation of X itself. It enables us to require integrality on the master variables, which is not valid in Equation (5). Vanderbeck [13] introduced the concept since “it allows for the development of a unifying and complete theoretical framework to deal with all relevant issues that arise in the implementation of a branch-and-price algorithm.” As we will see, he was in particular thinking of cutting planes and branching. We need the fact [9] that every integer $\mathbf{x} \in X$ can be written as an *integral* combination

$$\begin{aligned} \mathbf{x} &= \sum_{p \in P} \mathbf{x}_p \lambda_p + \sum_{r \in R} \mathbf{x}_r \lambda_r, \quad \sum_{p \in P} \lambda_p = 1, \\ \lambda &\in \mathbb{Z}_+^{|P|+|R|} \end{aligned} \quad (7)$$

with finite sets of *integer* points $\{\mathbf{x}_p\}_{p \in P} \subseteq X$ and *integer* rays $\{\mathbf{x}_r\}_{r \in R}$ of X . Note that we slightly abused the notation here since the set P of *generators* is usually not identical to the corresponding extreme points of the convexification approach, and rays in R are scaled to be integer. Substitution for $\mathbf{x}$ in Equation (3) yields an *integer* master problem

$$\min \sum_{p \in P} c_p \lambda_p + \sum_{r \in R} c_r \lambda_r$$

$$\begin{aligned} \text{subject to } & \sum_{p \in P} \mathbf{a}_p \lambda_p + \sum_{r \in R} \mathbf{a}_r \lambda_r \leq \mathbf{b} \\ & \sum_{p \in P} \lambda_p = 1 \\ & \lambda \in \mathbb{Z}_+^{|P|+|R|}, \end{aligned} \quad (8)$$

where integrality is now imposed on the master variables λ , and again $c_j = \mathbf{c}\mathbf{x}_j$ and $a_j = \mathbf{A}\mathbf{x}_j, j \in P \cup R$. Note that in fact $\lambda_p \in \{0, 1\}$ for $p \in P$. It is known [13] that the LP relaxation gives the same dual bound as problem (5). When solving problem (8) by column generation the pricing problem is the same as above, but it needs to be able to generate integer solutions in the interior of X . When X is bounded, Equation (8) is a linear integer program even when the original problem (3) has nonlinear cost function $c(\mathbf{x})$: Because of the convexity constraint, variables λ are binary, thus, $c(\mathbf{x}) = c(\sum_{p \in P} \mathbf{x}_p \lambda_p) = \sum_{p \in P} c_p \lambda_p$ turns into a linear objective function.

The discretization approach generalizes to a mixed integer set X in that integer variables are discretized and continuous variables are reformulated using the convexification approach [14]. For general integer variables this is not straight forward using the convexification approach, but in the important special case $X \subseteq [0, 1]^n$ of combinatorial optimization, convexification, and discretization coincide. Both approaches yield the same dual bound which equals that of Lagrangean relaxation (see **Relationship Among Benders, Dantzig-Wolfe, and Lagrangian Optimization** and Vanderbeck [15]).

Bordered Block-Diagonal Matrices

For many problems, $X = X_1 \times \dots \times X_K$ (possibly permuting variables), that is, X decomposes into $X_k = \{\mathbf{x}_k \in \mathbb{Z}_+^{n_k} \times \mathbb{Q}_+^{q_k} \mid D_k \mathbf{x}_k \leq \mathbf{d}_k\}$, $k = 1, \dots, K$, with all matrices and vectors of compatible dimensions and $\sum_k n_k = n$, $\sum_k q_k = q$. This is another way of saying that D can be brought into a block-diagonal form, so that the original problem (3) reads

$$\min \sum_k \mathbf{c}_k \mathbf{x}_k$$

$$\begin{aligned} \text{subject to } \sum_k A_k \mathbf{x}_k &\leq \mathbf{b} \\ \mathbf{x}_k &\in X_k, \quad k = 1, \dots, K. \end{aligned} \quad (9)$$

This is the classical situation for applying a Dantzig–Wolfe decomposition. Each $\mathbf{x}_k$ is expressed using Equation (4) or (7), with the introduction of λ_{kj} variables, $j \in P_k \cup R_k$, where $P = \bigcup_{k=1}^K P_k$ and $R = \bigcup_{k=1}^K R_k$. It is an important special case that some or all $(D_k, \mathbf{d}_k)$ are identical, for example, for bin packing, vertex coloring, or vehicle-routing problems. This implies a symmetry since “the same” solution can be expressed in many different ways by permuting the k indices. Symmetry is beautiful in many areas of mathematics, however, for an integer program it may be a major source of inefficiency in a branch-and-bound algorithm and should be avoided by all means. Typically, one aggregates (sums up) the λ_{kp} variables, substituting $v_p := \sum_k \lambda_{kp}$, and adding up the K convexity constraints. Extreme rays need no aggregation. Choosing a representative P_1 , we obtain the *aggregated* extended formulation

$$\begin{aligned} \min \quad & \sum_{p \in P_1} c_p v_p + \sum_{r \in R} c_r \lambda_r \\ \text{subject to } \quad & \sum_{p \in P_1} \mathbf{a}_p v_p + \sum_{r \in R} \mathbf{a}_r \lambda_r \leq \mathbf{b} \\ & \sum_{p \in P_1} v_p = K \quad (10) \\ & \mathbf{v} \in \mathbb{Z}_+^{|P_1|} \\ & \lambda \in \mathbb{Z}_+^{|R|}, \end{aligned}$$

here in the discretization version. This also condenses the original $\mathbf{x}_k$ variables into aggregated original variables $\mathbf{z} = \sum_k \mathbf{x}_k$.

Extended Reformulations

Lifting a mixed integer problem to a higher-dimensional space, obtaining a stronger formulation there, and projecting this back to the original variables’ space is a well-known concept in integer programming (see *Symmetry Handling in Mixed-Integer Programming, Disjunctive Programming*). Not only in the context

of branch-and-price it is helpful to know some basic ideas. The very recommendable survey [16] presents decomposition approaches in this context.

A polyhedron $Q = \{(\mathbf{x}, \lambda) \in \mathbb{R}^n \times \mathbb{R}^\ell \mid A\mathbf{x} + L\lambda \leq \mathbf{b}\}$ is called an *extended formulation* of a polyhedron $O \subseteq \mathbb{R}^n$ if Q can be projected to O , that is, if $O = \text{proj}_{\mathbf{x}}(Q)$, where $\text{proj}_{\mathbf{x}}(Q)$ denotes the projection of Q on the $\mathbf{x}$ variables, that is, $\text{proj}_{\mathbf{x}}(Q) = \{\mathbf{x} \in \mathbb{R}^n \mid \exists \lambda \in \mathbb{R}^\ell : (\mathbf{x}, \lambda) \in Q\}$. Polyhedron Q is an extended formulation of the integer set X if $X = \text{proj}_{\mathbf{x}}(Q) \cap \mathbb{Z}_+^n$. More generally, Q may itself be a mixed integer set, and we call Q an extended formulation of the mixed integer set X if $X = \text{proj}_{\mathbf{x}}(Q)$. The discretization approach provides an example. We also speak of a *problem* being an extended formulation, for example, we call the linear relaxation of the master problem (5) an extended formulation of the original problem (3).

As stated above, extended formulations are typically stronger than their original counterparts, and the special interest in Dantzig–Wolfe type extended reformulations Q of mixed integer sets X lies in the fact that they are *tight*, that is, $\text{proj}_{\mathbf{x}}(Q) = \text{conv}(X)$. That is, they are best in a well-defined sense at the expense that they may contain an exponential number of variables.

It is of main interest in our context that some experience and creativity with projections and extended formulations may help us reformulating a problem *before* a Dantzig–Wolfe decomposition is applied, be it implicit or explicit. This becomes important when formulating cutting planes (see the section titled “Cutting Planes”) and branching rules (the section titled “Branching”). In order to provide some intuition, consider a flow-based formulation for the minimum spanning tree problem in a graph $G = (V, E)$ where one sends one unit of flow from a designated root node to all other nodes, that is, $|V| - 1$ units in total. An integer variable x_{ij} represents the amount of flow on edge $(i, j) \in E$, and binary variables y_{ij} indicate whether $(i, j) \in E$ is in the spanning tree. Edge $(i, j) \in E$ may carry flow only when it is part of the tree, that is, $x_{ij} \leq (|V| - 1) \cdot y_{ij}$. This “big- M ” formulation can be much improved by extending the

formulation by introducing a separate flow commodity $k = 1, \dots, |V|$ for each node, that is, reformulate $x_{ij} = \sum_k x_{ij}^k$. The above mentioned constraint becomes $x_{ij}^k \leq y_{ij}$ which obviously better reflects the integrality of the y_{ij} variables, and thus gives stronger branching and cutting opportunities.

Reducing problem symmetry can be another reason to consider an extended formulation [17]. For problems like bin packing, graph coloring, and many others, binary variables x_{ij} assign items i to identical entities j . The symmetry in index j can be broken, for example, by binary variables z_{ij} which reflect the assignment of items i and j to the same entity but not items $i < k < j$. Cutting planes are reported to be effective at the cost of a more complicated pricing problem.

Reversing Dantzig–Wolfe Decomposition

Column generation can be applied without a prior decomposition. Examples are set covering or set partitioning problems like in the classical cutting stock problem or in vehicle and crew scheduling (see the section titled “Vehicle Routing and Scheduling” in this encyclopedia). One directly formulates an integer master problem (1) together with a pricing problem (2). Without a decomposition, there is no *original* problem. However, as we describe later, such an original problem can be very helpful in designing branching rules and cutting planes. Consequently, we would like to construct a corresponding original problem from Equations (1) and (2). That is, in a sense, one aims at *reversing* the Dantzig–Wolfe decomposition. Under a mild assumption, which is typically true, this can be done [18]. The idea exploits the fact that the pricing problem is formulated in original variables, for example, when the pricing problem constructs a path in a network, the decisions taken are typically whether an edge is included in the path or not. Conforming with our previous notation, we assume that we know an integer upper bound K on $\sum_{j \in J} \lambda_j$ in Equation (1) (the maximum number of vehicles, paper rolls, bins, etc.). When the zero column $\mathbf{a}_0 = \mathbf{0}$ has cost $c_0 = 0$, we can assume equality constraints in an original formulation. We duplicate the pricing

problem’s domain K times, that is, we set $X_k = X$, $k = 1, \dots, K$, and obtain a bordered block-diagonal form

$$\begin{aligned} \min \quad & \sum_{k=1}^K c(\mathbf{x}_k) \\ \text{subject to} \quad & \sum_{k=1}^K a(\mathbf{x}_k) = \mathbf{b} \\ & \mathbf{x}_k \in X_k \quad k = 1, \dots, K. \end{aligned} \quad (11)$$

Performing a Dantzig–Wolfe decomposition on Equation (11) one obtains a formulation equivalent to Equation (1) where each of the K pricing problems contributes, due to the convexity constraints, at most one unit to the master solution. Note that this introduces the symmetry of identical subproblems by design of the construction and one needs to aggregate the $\mathbf{x}_k$ variables. We have produced a projection to the variables implicitly given in the pricing problem. This is just one option; symmetry avoiding projections are preferable, for example, by explicitly producing different pricing problems.

CUTTING PLANES

Just as in standard branch-and-cut adding valid inequalities can strengthen the LP relaxation, yielding what is known as *branch-price-and-cut*. In the earlier days, this combination has been considered problematic, since the pricing problem must be aware of the coefficients in cutting planes as these need to be lifted when new variables are generated. With the introduction of the two viewpoints presented in this section the notion of *compatibility* became obsolete.

In the convexification approach (Eq. 5) integrality is required on the $\mathbf{x}$ variables just as in the original problem (3). Thus, it is only natural to formulate valid inequalities on these variables. On the other hand, remembering the motivation for extended formulations (see the section titled “Extended Reformulations”), this ignores the potential of the higher dimensional space, or in other words: We would like to formulate valid inequalities on the integer master variables

of the discretization reformulation (8) as well. Our presentation follows Desaulniers *et al.* [19], and several examples can be found therein.

Cutting Planes on the Original Variables

Assume that we know a set $F\mathbf{x} \leq \mathbf{f}$ of inequalities valid for the original problem (3), that is,

$$\begin{aligned} \min \quad & \mathbf{c}\mathbf{x} \\ \text{subject to} \quad & A\mathbf{x} \leq \mathbf{b} \\ & F\mathbf{x} \leq \mathbf{f} \\ & \mathbf{x} \in X \end{aligned} \quad (12)$$

has the same integer feasible solutions. Via a Dantzig–Wolfe reformulation these inequalities directly transfer to the master problem, both in convexification and discretization

$$\sum_{p \in P} \mathbf{f}_p \lambda_p + \sum_{r \in R} \mathbf{f}_r \lambda_r \leq \mathbf{f} \quad (13)$$

with the linear transformations $\mathbf{f}_j = F\mathbf{x}_j$ for $j \in P \cup R$. The dual variables α of the additional inequalities (13) can be easily taken care of in the pricing problem, (6)

$$\min\{\mathbf{c}\mathbf{x} - \pi A\mathbf{x} - \alpha F\mathbf{x} - \pi_0 \mid \mathbf{x} \in X\} \quad (14)$$

or in other words, with the dynamic addition of valid inequalities formulated in the original $\mathbf{x}$ variables, only the pricing problem’s objective function needs to be updated. We may alternatively enforce the cutting planes in the pricing problem by reducing its domain to $X_F = \{\mathbf{x} \in X \mid F\mathbf{x} \leq \mathbf{f}\}$. The reason for doing so is that inequalities added to X are convexified when we solve the pricing problem as an integer program, and thus we may hope for a stronger dual bound. The pricing problem (6) becomes

$$\min\{\mathbf{c}\mathbf{x} - \pi A\mathbf{x} - \pi_0 \mid \mathbf{x} \in X_F\}, \quad (15)$$

which, interestingly, may sometimes be of the same structure as before the modification. Sets P and R need to be updated in the master problems (5) or (8); moreover, variables λ_j with $F\mathbf{x}_j > \mathbf{f}$, $j \in P \cup R$, have to be eliminated.

Generic cutting planes (see also the section titled “Automatic Convexification” in this encyclopedia) formulated on the original $\mathbf{x}$ variables sometimes seem to have little or no effect on improving the usually already strong dual bound (see *Decomposition Methods for Integer Programming*). This may also be due to the fact that usually no basic solution to the original problem is available on which several generic cutting planes rely (a crossover might help here). Currently, problem-specific valid inequalities are the alternative to go.

It is known that separation of particularly structured (e.g., integer) points may be considerably easier than separating arbitrary fractional solutions. This motivates to use the decomposition to aid separation: A fractional master solution is a convex combination of integer solutions to the pricing problems which can be recovered and separated separately. In Ralphs and Galati [20] this is called *structured separation* or *decompose and cut*.

Cutting Planes on the Master Variables

In many applications, and in particular, in the discretization approach, the master variables are integer variables. It is clear that not every inequality in the master λ variables can be derived from the original $\mathbf{x}$ variables via a Dantzig–Wolfe decomposition, and this complicates matters as we will see. Assume that we already separated a set $G\lambda \leq \mathbf{g}$ of valid inequalities in the master problem, that is,

$$\begin{aligned} \min \quad & \sum_{p \in P} c_p \lambda_p + \sum_{r \in R} c_r \lambda_r \\ \text{subject to} \quad & \sum_{p \in P} \mathbf{a}_p \lambda_p + \sum_{r \in R} \mathbf{a}_r \lambda_r \leq \mathbf{b} \\ & \sum_{p \in P} \mathbf{g}_p \lambda_p + \sum_{r \in R} \mathbf{g}_r \lambda_r \leq \mathbf{g} \\ & \sum_{p \in P} \lambda_p = 1 \\ & \lambda \in \mathbb{Z}_+^{|P|+|R|}. \end{aligned} \quad (16)$$

The dual variables β of these cuts need to be respected when calculating reduced costs in the pricing problem—if we do not—we

may regenerate “cut off” variables and end up in an infinite loop of separation and pricing. Certainly, we would lose the strength of a cut if we did not lift it. If we think of the cuts’ coefficients of a variable $\lambda_j, j \in P \cup R$, as the result of a function $\mathbf{g}_j = g(\mathbf{a}_j)$, the pricing problem reads

$$\min\{\mathbf{c}\mathbf{x} - \pi\mathbf{A}\mathbf{x} - \beta g(\mathbf{A}\mathbf{x}) - \pi_0 \mid \mathbf{x} \in X\}. \quad (17)$$

Function g can be quite complicated; it may be nonlinear as in the case of a Chvátal–Gomory rank-1 cut [9,21] with rational multipliers $\mathbf{u} \in [0, 1]^n$

$$\sum_{p \in P} \lfloor \mathbf{u}\mathbf{a}_p \rfloor \lambda_p + \sum_{r \in R} \lfloor \mathbf{u}\mathbf{a}_r \rfloor \lambda_r \leq \lfloor \mathbf{u}\mathbf{1} \rfloor.$$

It can be helpful from a conceptual viewpoint to introduce new variables $\mathbf{y} = g(\mathbf{A}\mathbf{x})$ to compute the coefficients from a solution to the pricing problem. An example is to introduce new resources, one for each cutting plane, in the resource-constrained shortest path pricing problem typically used in vehicle-routing problems. As just mentioned we cannot hope that g is linear, but if it is, that is, $\mathbf{y} = g(\mathbf{A}\mathbf{x}) = F\mathbf{x}$ we immediately see that cutting planes on the master variables contain those which can be derived from the original variables.

Desaulniers *et al.* [19] note that introducing additional variables in the pricing problem hints at an extended original (possibly nonlinear) formulation from which cutting planes in the master variables follow Dantzig–Wolfe decomposition (the section titled “Reversing Dantzig–Wolfe Decomposition”):

$$\begin{aligned} \min \quad & \mathbf{c}\mathbf{x} \\ \text{subject to} \quad & \mathbf{A}\mathbf{x} \leq \mathbf{b} \\ & \mathbf{y} \leq \mathbf{g} \\ & \mathbf{x} \in X \\ & \mathbf{y} = g(\mathbf{A}\mathbf{x}), \end{aligned} \quad (18)$$

where $\mathbf{y} \leq \mathbf{g}$ remains in the master problem while $\mathbf{y} = g(\mathbf{A}\mathbf{x})$ goes in the pricing problem.

Cutting planes on the master variables is a recent topic. So far a successful separation of clique inequalities [22], Chvátal–Gomory rank-1 cuts [21] (and subsets [23]) has been reported only for a very few problems. The modified subproblems become harder, in particular, when the computation of cut coefficients requires severe modifications in the pricing problem.

Using an Extended Formulation

As noted in the section titled “Extended Reformulations”, extended formulations may give rise to tighter relaxations as they may “better reflect integrality requirements of the problem.” Column generation based algorithms often offer natural candidates for such extended formulations when the pricing problem is solved via dynamic programming. Simple examples are the bin packing [24] or cutting stock [25] master problems where the subproblem is a knapsack problem. The dynamic program for the knapsack problem with capacity B can be formulated as a longest path problem in an acyclic network of pseudopolynomial size, namely with B nodes representing the used capacity of the knapsack. Arcs between vertices i and j represent picking an item of size $j - i$ when already a capacity of i is used. Zero-cost arcs between consecutive vertices represent unused capacity. Using these arcs as variables for a reformulation of the pricing problem one obtains a network flow problem.

In general, variables represent state transitions of the dynamic program and this may allow to formulate complex cutting planes, expressed in a simple way and without significant changes to the pricing problem. In the capacitated vehicle-routing problem [26] this approach leads to variables x_{ij}^d which state that some vehicle arrives in j , coming from i , with a remaining capacity of d . Besides such “capacity-indexed formulations,” for example, time-indexed formulations are used in scheduling problems. Flow conservation reformulated in these variables gives what they call a *base equality* from which many families of valid inequalities can be derived.

There is good experience with such kinds of cutting planes also for the capacitated

minimum spanning tree problem [27], machine scheduling problems [28], and several more [16].

BRANCHING

Even though branching decisions can be imposed by additional constraints (which we know how to do) we still have to *find* good branching rules. Disjunctive branching on the master variables is either not feasible (in convexification nobody asks for integer master variables) or not advisable: In discretization branching a master variable to zero has essentially no effect on the dual bound, while the up-branch significantly changes the solution, and thus potentially the dual bound. This produces an unbalanced search tree. Moreover, down-branching forbids certain solutions to the pricing problem to be regenerated. This problem brought up the notion of *compatibility* between pricing problem and branching rule which means that the pricing problem should not complicate after branching. Working simultaneously with original and master formulation, that is, branching on original variables helped a lot, but introduces new problems, in particular, when pricing problems are identical; we follow the classification of Vanderbeck and Wolsey [16], which contains a thorough exposition. Let λ^* denote an optimal solution to the restricted master problem.

Convexification: Branching on Original Variables

When all pricing problems are distinct, in particular, when there is only one pricing problem, the convexification approach with its integrality requirement on original variables is the natural way to go. As is immediate by Equation (5), branching candidates are all original x_i variables with $x_i^* = \sum_{j \in P \cup R} x_{ji} \lambda_j^* \notin \mathbb{Z}_+$, where x_{ji} denotes the i th component of $\mathbf{x}_j$, $j \in P \cup R$. Dichotomic branching on x_i creates two new problems, on the down-branch by imposing $x_i \leq \lfloor x_i^* \rfloor$, and on the up-branch by requiring $x_i \geq \lceil x_i^* \rceil$. There are two general options on how to enforce the branching decision, either in the

master problem or in the pricing problem. We discuss only the down-branch here, the up-branch is handled analogously.

Master Problem. The branching constraint $x_i \leq \lfloor x_i^* \rfloor$ is reformulated via convexification, that is, we add to the master problem (5) the constraint

$$\sum_{p \in P} x_{pi} \lambda_p + \sum_{r \in R} x_{ri} \lambda_r \leq \lfloor x_i^* \rfloor. \quad (19)$$

The additional dual variable α_i is respected in the pricing problem as in Equation (14), that is, only its objective function needs modification. However, no integer points in the interior of $\text{conv}(X)$ can be obtained from the pricing problem, and we may miss an optimal solution in the case of general integer variables $\mathbf{x}$.

Pricing Problem. The second option is to change the bound $x_i \leq \lfloor x_i^* \rfloor$ directly in the pricing problem, which forbids the generation of extreme points and rays which violate the branching decision. Master variables already present but incompatible with the branching decision need to be eliminated. This can be done by adding

$$\begin{aligned} \sum_{\substack{j \in P \cup R: \\ x_{ji}=1}} \lambda_j &= 0 \quad \text{or equivalently,} \\ \sum_{\substack{j \in P \cup R: \\ x_{ji}=0}} \lambda_j &= 1, \end{aligned} \quad (20)$$

to the master problem (5) which can be seen as modifying the convexity constraint (its dual variable is still denoted by π_0). The pricing problem then becomes

$$\min\{\mathbf{c}\mathbf{x} - \pi\mathbf{A}\mathbf{x} - \pi_0 \mid \mathbf{x} \in X \cap \{\mathbf{x} \mid x_i \leq \lfloor x_i^* \rfloor\}\}. \quad (21)$$

This may complicate the pricing problem, however, if it stays tractable, this option is to be preferred. The main reason is the potentially stronger dual bound from the master

problem relaxation since the bound change is convexified

$$\begin{aligned} & \min\{\mathbf{c}\mathbf{x} \mid \mathbf{A}\mathbf{x} \leq \mathbf{b}, \mathbf{x} \in \text{conv}(X), x_i \leq \lfloor x_i^* \rfloor\} \\ & \leq \min\{\mathbf{c}\mathbf{x} \mid \mathbf{A}\mathbf{x} \leq \mathbf{b}, \mathbf{x} \in \text{conv}(X) \\ & \quad \cap \{\mathbf{x} \mid x_i \leq \lfloor x_i^* \rfloor\}\}. \end{aligned} \quad (22)$$

Furthermore, adding disjunctive bounds to the pricing problem, that is, partitioning its domain allows to generate points in the interior of $\text{conv}(X)$ after branching.

Our presentation discussed the root node but both options directly extend to any node in the tree. One only needs to keep track of the modifications to the master and pricing problems which are local to subtrees. Both options generalize to the case of mixed integer programs.

Discretization: Avoiding the Symmetry

Branching on original variables works well when all pricing problems are distinct since

$$\mathbf{x}_k = \sum_{p \in P_k} \mathbf{x}_p \lambda_{kp}, \quad (23)$$

defines a unique projection from the λ variables into the original $\mathbf{x}$ variable space.

As pointed out in the section titled “Bordered Block-Diagonal Matrices”, the case of identical pricing problems bears a symmetry which should be avoided. One may aggregate original variables $\sum_k \mathbf{x}_k = \mathbf{z}$ and obtain a single pricing problem as above. Branching decisions disaggregate variables again and create distinct pricing problems [18]. However, as any permutation of the index set $\{1, \dots, K\}$ gives an equivalent solution, this does not eliminate the symmetry in the $\mathbf{x}_k$ variables [29].

Consider the aggregated master problem (10) of the discretization approach. Disaggregation of the variables $v_p = \sum_k \lambda_{kp}$ and using Equation (23) to obtain an original $\mathbf{x}$ solution is neither unique nor does integrality of $\mathbf{v}$ necessarily imply integrality of $\mathbf{x}$. The trick to avoid these shortcomings and symmetry at the same time is to present a projection from the master into the original variable space which does not use the one-to-one correspondence (Eq. 23) between λ_{kp} and

$\mathbf{x}_k$ variables. In other words, the grouping of λ variables is only implicit. Vanderbeck [29] (see also Vanderbeck and Wolsey [16]) proposed to obtain values $\mathbf{x}_1^*, \dots, \mathbf{x}_K^*$ (in that order) by summing variables λ_{kp} in lexicographic order of the corresponding $\mathbf{x}_p$, where $\mathbf{x}_q < \mathbf{x}_p$ means that $\mathbf{x}_q$ precedes $\mathbf{x}_p$ in that ordering. For all $k = 1, \dots, K$ and $p \in P$ let

$$\begin{aligned} \lambda_{kp}^* = \min & \left\{ 1, v_p - \sum_{\kappa=1}^{k-1} \lambda_{\kappa p}^*, \right. \\ & \left. \max \left\{ 0, k - \sum_{q: \mathbf{x}_q < \mathbf{x}_p} v_q^* \right\} \right\}. \end{aligned} \quad (24)$$

We obtain $\mathbf{x}_k^* = \sum_{p \in P} \mathbf{x}_p \lambda_{kp}^*$. The lexicographic sorting guarantees that we always work with a unique representative solution $\mathbf{x}$ out of the many symmetric possibilities. This is a standard trick which has been used in symmetry breaking of integer programs recently [30].

Aggregate Original Variables. When there happens to be a fractional aggregate original variable value $y_i^* = \sum_{p \in P} x_{pi} v_p^* \notin \mathbb{Z}_+$, which need not be the case in general, branching can be performed on such a variable by imposing

$$\begin{aligned} y_i &= \sum_{p \in P} x_{pi} v_p^* \leq \lfloor y_i^* \rfloor \quad \text{or} \\ y_i &= \sum_{p \in P} x_{pi} v_p^* \geq \lceil y_i^* \rceil \end{aligned} \quad (25)$$

in the master. This only affects the pricing problem’s objective function but this may considerably change its character. This simple rule may give only little improvement on the dual bound [16].

Auxiliary Original Variables. When the previous rule fails, that is, when an integer $\mathbf{y}$ does not yield an integer $\mathbf{x}$ (“the set of branching objects is not rich enough” [16]), one may try to work with an extended original formulation by introducing auxiliary variables to branch on, see the section titled “Extended Reformulations.” As an example consider the

set partitioning problem

$$\min \left\{ \sum_{p \in P} \mathbf{c} \mathbf{x}_p v_p \mid \sum_{p \in P} \mathbf{x}_p v_p = \mathbf{1}, \right. \\ \left. \sum_{p \in P} v_p = K, v_p \in \{0, 1\}^{|P|} \right\}. \quad (26)$$

Many problems lead to such a Dantzig–Wolfe reformulation like bin packing or vertex coloring. For the latter problem, original variables $x_{ki} \in \{0, 1\}$ state whether vertex i receives color k and columns $\mathbf{x}_p$ correspond to independent sets in the underlying graph. Aggregate variables $y_i^* = \sum_{p \in P} x_{pi} v_p^* = 1$ for any master solution, so the previous rule does not apply. However, it is well-known that in a fractional master solution there must exist rows i and j with

$$\sum_{\substack{p \in P \\ x_{pi} = x_{pj} = 1}} v_p^* =: w_{ij}^* \notin \{0, 1\}. \quad (27)$$

We (conceptually) introduce w_{ij} as auxiliary variables in the original problem for every pair (i, j) of vertices (and in the pricing problem as well) and branch on these variables. It may not be straight forward to impose the branching decision in the pricing problem directly; Ryan and Foster branching [31] is an example in which $w_{ij} \in \{0, 1\}$ is enforced by letting $x_i = x_j$ in one branch and $x_i \neq x_j$ in the other. When the pricing problem is solved via a combinatorial algorithm, often a dynamic program, this naturally suggests an extended formulation of the pricing problem which translates to an extended original formulation [16], see also the section titled “Using an Extended Formulation.”

Nested Partition of the Convexity Constraint.

The most general rule is to split the master variables by modification of the convexity constraint [29]. If

$$\sum_{p \in P: x_{pi} \geq \ell_i} v_p = \delta \notin \mathbb{Z}_+ \quad (28)$$

for an index i (corresponding to original variable x_i) and an integer bound ℓ_i , one creates

two branches with

$$\sum_{p \in P: x_{pi} \geq \ell_i} v_p \geq \lceil \delta \rceil \quad \text{or} \\ \sum_{p \in P: x_{pi} \leq \ell_i - 1} v_p \geq K - \lfloor \delta \rfloor. \quad (29)$$

The pricing problems must respect the variable bounds $x_i \geq \ell_i$ and $x_i \leq \ell_i - 1$, respectively. In order to guarantee a fractional δ in Equation (28) one may need to impose bounds on a set S of original variables. In fact, such sets are found recursively, and this generalizes the partition in Equation (29) in a nested way, producing more than two branches in general. The pricing problems must respect the bounds on variables in S and the respective complementary sets. There are several technical details to consider for which we refer to Vanderbeck [29].

This last rule provides the strongest dual bound among the above proposals and implies the smallest impact in the pricing problem (only bound changes). It should be noted that points in the interior of $\text{conv}(X)$ can be generated with this generic rule and that the depth of the search tree is polynomially bounded.

IMPLEMENTATION ISSUES

Even when the whole lot of work of implementing a branch-price-and-cut algorithm will pay off, it is a whole lot of work, even in 2010. We have seen that the freedom of choice can be enormous and some experience will certainly help. Nonetheless, it has never been easier than today with the great body of literature available.

At least when working with a convexification approach, one needs access to the values of the original variables. A trivial (but probably not efficient) way of doing this is to keep the constraints linking them to the master variables in the formulation (keeping the master constraints on the original variables is called the *explicit master* [17]). This facilitates, for example, branching on binary original variables since a simple bound change on the $\mathbf{x}$ variables implies eliminating incompatible master variables since their upper bounds are automatically changed to zero.

Even though an original (fractional) solution $\mathbf{x}^*$ is available, there is a drawback that has not been satisfactorily addressed so far: Typically, $\mathbf{x}^*$ is not a basic solution. This is important since several generic cutting planes and primal heuristics rely on that. Performing a crossover has been suggested (Matthew Galati in personal communication referred to John Forrest) as a possible remedy but there are no experiences reported on this yet.

Frameworks

There are several frameworks which support the implementation of branch-and-price algorithms like ABACUS [32], BCP [33], MINTO [34], SCIP [35], and SYMPHONY [36], to name only a few. In addition there are codes which perform a Dantzig–Wolfe decomposition of a general (mixed) integer program, and handle the resulting column generation subproblems in a generic way. BaPCod [37] is a “prototype code that solves mixed integer programs (MIPs) by application of a Dantzig–Wolfe reformulation technique.” The COIN-OR initiative (www.coin-or.org) hosts a generic decomposition code, called DIP [38] (formerly known as DECOMP), which is a “framework for implementing a variety of decomposition-based branch-and-bound algorithms for solving mixed integer linear programs” as described in Ralphs and Galati [20]. The constraint programming G12 project develops “user-controlled mappings from a high-level model to different solving methods,” one of which is branch-and-price [39]. The attempt to turn the branch-price-and-cut framework SCIP into a branch-price-and-cut solver is called GCG [40].

When Everything Fails . . .

Many problems which are approached by branch-price-and-cut are so large and complex that optimal solutions are out of reach in a reasonable computation time. What do we do then? The most honorable answer to that is: Research your problem! Is there any particular structure you can exploit, for example, by using a combinatorial algorithm to solve your pricing problems (instead of

solving them as MIPs); by formulating cutting planes; or by rethinking the entire Formulation. After all, this is what drives the innovations! The most practicable answer probably is to run a profiler to check where your code spends the CPU time, and search the bag of tricks for accelerating the weak spots. In particular, you may consider acceleration techniques [41] for solving the relaxations by column generation. The quickest (and sometimes the most promising, but certainly the dirtiest) answer is to go with a heuristic. In particular, in practical applications you may not need to close the last percents of the optimality gap. Many practitioners will use *price-and-branch*, that is, column generation is used only in the root node. In particular, if the problem is of set covering type (which it often is), one may branch on master variables and do not care about the theory. This is not elegant, but it often works. However, if the solver allows this, one should try to fix some variables (e.g., by branching) and generate further columns; this usually perceptively improves the solution quality.

A REMARK AND RECOMMENDATIONS FOR FURTHER READING

A final remark on the notion *branch-price-and-cut*. There is consent on using *branch-and-cut* and *branch-and-price*; so consequently the integration was named *branch-and-cut-and-price* in the first references. Adam Letchford (personal communication, 2005) remarked that a better style English is to omit the first *and*. In addition, exchanging *cut* and *price* reflects their order when solving the relaxation in each node, so we suggest to use *branch-price-and-cut*.

The classical—by now a bit outdated—survey on branch-and-price is by Barnhart *et al* [42]. The book [43] on column generation is, in fact, a book on branch-and-price and contains a lot of applications, in particular, vehicle routing, the cutting stock problem, and machine scheduling. The book also contains an introductory text to the topic [44] with a focus on convexification. Implementation issues can be found in Vanderbeck [45].

Branch-width, introduced by Robertson and Seymour [1], is a general concept to describe the difficulty of decomposing finitely many objects into a tree-like structure by partitioning them into two parts recursively, while maintaining each cut to have small connectivity measure. Branch-width normally is defined for graphs or hypergraphs, as discussed by Robertson and Seymour [1], but it is easy to be extended for other combinatorial objects such as matroids and any integer-valued symmetric submodular functions.

Roughly speaking, branch-decomposition is a description on a maximal collection of nonoverlapping partitions of a finite set E . The width of a branch-decomposition is the maximum “complexity” of each part appearing in the branch-decomposition, where the “complexity” is given by some function on subsets of E . The branch-width is the minimum possible width over all possible branch-decompositions of E . Precise definition will be discussed in the following section.

To show that branch-width is small, we need to illustrate how to decompose nicely; in other words, we need to present a branch-decomposition of small width in order to certify that branch-width is small. On the other hand, if we want to certify that branch-width is large, a naive approach would be trying all possible branch-decompositions, which is too time-consuming. For that purpose we use tangles. A tangle is a dual notion of branch-width which certifies why the branch-width

is large. It was also defined by Robertson and Seymour in the same article.

In this article, we explain those definitions and list their algorithmic properties.

BRANCH-WIDTH

Usually branch-width is defined for graphs and hypergraphs. But for the sake of generality, we define it for integer-valued symmetric submodular functions first. An integer-valued function f on subsets of a finite set E is *symmetric* if $f(X) = f(E - X)$ for all subsets X of E and f is called *submodular* if $f(X) + f(Y) \geq f(X \cap Y) + f(X \cup Y)$ for all subsets X, Y of E .

Let us now assume that an integer-valued symmetric submodular function f on subsets of a finite set E is given. We call a tree *subcubic* if every vertex has degree 3 or 1. A *branch-decomposition* (T, τ) of f consists of a subcubic tree T and a bijection τ from the set of leaves of T to E . Then the *width* of an edge e of T is defined to be $f(\tau(A_e))$ when (A_e, B_e) is a partition of the set of leaves of T given by $T \setminus e$. Notice that this is well-defined because $f(\tau(A_e)) = f(\tau(B_e))$. The *width* of a branch-decomposition (T, τ) is the maximum width of all edges of T . The *branch-width* of f , denoted by $\text{bw}(f)$, is the minimum width of all possible branch-decompositions of f . If $|E| \leq 2$, then there are no branch-decompositions and so we just define branch-width to be $f(\emptyset)$.

By choosing an appropriate set E and an integer-valued symmetric submodular function, we can generate various notions of width parameters. Let us present some of them here.

Branch-Width of Graphs and Hypergraphs

Branch-width was first introduced by Robertson and Seymour [1] for graphs and hypergraphs. For a graph (or a hypergraph) G and a subset X of edges, let $\eta_G(X)$ be the number of vertices which are incident with an edge in X as well as an edge in $E(G) - X$. It is

studied by Dharmatilake [5] and has played an important role in the development of the matroid structure theory by Geelen *et al.* [6,7].

If a graph G has at least one cycle of length at least 2, then G and its cycle matroid $M(G)$ has the same branch-width, shown by Hicks and McMurray, Jr. [8] and independently by Mazoit and Thomassé [9] later.

Carving-Width of Graphs

Carving-width of graphs was introduced by Seymour and Thomas [10]. For a graph G and a subset A of vertices, we write $\delta_G(A)$ to denote the set of all edges joining a vertex in A with a vertex in $V(G) - A$. Let $p_G(X) = |\delta_G(A)|$. Again p_G is symmetric submodular. The *carving-width* of a graph is the branch-width of p_G . Carving-width is a useful tool for the branch-width of a planar graph because the branch-width of a planar graph is exactly half of the carving-width of its medial graph [10].

TANGLES

Tangles are introduced as a means to certify that the branch-width is large. If we wish to convince that branch-width is small, we can simply present a branch-decomposition of small width. However, we do not want to try all possible branch-decompositions in order to convince that branch-width is big. Tangles play such a role; if a tangle is presented, then no branch-decomposition of small width can exist.

For an integer-valued symmetric submodular function f on subsets of a finite set E , an f -tangle of order $k + 1$ is a collection $\mathcal{T}$ of subsets of E satisfying the following three axioms.

- (T1) For all $A \subseteq E$, if $f(A) \leq k$, then either $A \in \mathcal{T}$ or $E - A \in \mathcal{T}$.
- (T2) If $A, B, C \in \mathcal{T}$, then $A \cup B \cup C \neq E$.
- (T3) For all $e \in E$, we have $E - \{e\} \notin \mathcal{T}$.

Let us call a set X in a tangle $\mathcal{T}$ *small* and the complement $E - X$ *large*. Informally speaking, a large set is a “highly connected” set so that it is impossible to decompose

a large set properly to construct a branch-decomposition of small width. In Fig. 2, we illustrate a large set in a tangle of order 3 for the Petersen graph. Edges shown in Fig. 2 form a large set.

Robertson and Seymour introduced tangles and proved lots of useful properties. The following duality theorem is very useful. It was implicitly proved by Robertson and Seymour [1, (3.5)]. Geelen *et al.* [11, Theorem 3.2] rewrote the proof.

Theorem 1. *Let f be an integer-valued symmetric submodular function on subsets of E . Then no f -tangle of order $k + 1$ exists if and only if the branch-width of f is at most k .*

This allows us to define the branch-width from tangles; the branch-width is equal to the maximum k such that a tangle of order k exists. And to show that $\text{bw}(f) = k$ for an integer k , we frequently construct both a branch-decomposition of width k for an upper bound on the branch-width and an f -tangle of order k for a lower bound.

Providing a lower bound for the branch-width is generally harder than finding an upper bound. Therefore, much of the work to find the exact branch-width is usually devoted to finding a tangle. For the branch-width of the $n \times n$ grid, Kleitman and Saks (in Ref. 1) presented a tangle of order n , thus proving that the branch-width of the $n \times n$ grid is n . Geelen *et al.* [12] used tangles to prove that the branch-width of the cycle matroid of the $n \times n$ grid is n . For the rank-width of the $n \times n$ grid G , Jelínek [13]

Figure 2. A “large” part in an order-4 tangle of the Petersen graph.

presented a ρ_G -tangle of order $n - 1$, thus certifying that the rank-width of the $n \times n$ grid is $n - 1$.

Roughly speaking a set of maximal tangles is used to identify highly connected pieces in a combinatorial structure. Robertson and Seymour [1] (see also Geelen *et al.* [12]) showed that any symmetric submodular function on E has at most $(|E| - 2)/2$ maximal tangles, which are displayed by a tree structure. That tree structure has been used to describe and prove the structure of graphs or binary matroids without some fixed minor.

COMPUTING BRANCH-WIDTH

One of the most natural questions after defining branch-width is the complexity of computing the branch-width of integer-valued symmetric submodular functions on subsets of a finite set E . Since we may need 2^n values of f for all subsets of E in order to input f , we will assume that f is given by an oracle so that we can query the oracle to compute $f(X)$ for the input set X at a unit time.

Hardness Results

In general, it is hard to decide whether branch-width is at most k for an integer-valued symmetric submodular function f given by an oracle and an input k in time polynomial in n . Seymour and Thomas [10] showed that it is NP-hard to compute branch-width or carving-width of a graph. Kloks *et al.* [14] proved that computing branch-width is NP-hard even for bipartite graphs or split graphs. Computing branch-width of a matroid given as a matrix representation is also NP-hard and computing rank-width of a graph is also NP-hard, because of the relationship between branch-width of graphs and branch-width of cycle matroids [8,9].

Exact Exponential-Time Algorithms

For the efficient exact algorithm, Oum [15] found an $O^*(2^{|E|})$ -time algorithm to compute the branch-width of any integer-valued symmetric submodular function f given by an oracle as above. (Here, $O^*(2^{|E|})$ means

$O(2^{|E|}|E|^{O(1)})$.) It is not known whether $O^*(2^{|E|})$ can be improved to $O^*(c^{|E|})$ for some $1 < c < 2$. For graphs $G = (V, E)$, branch-width can be computed in time $O^*((2\sqrt{3})^{|V|})$, shown by Fomin *et al.* [16].

Exact Polynomial-Time Algorithms for Special Classes

When we restrict inputs, the branch-width can sometimes be computed efficiently. Branch-width can be computed in polynomial time for circular arc graphs [17] and interval graphs [14,18]. For planar graphs, branch-width and carving-width can be computed in polynomial time, shown by Seymour and Thomas [10]. More precisely, their algorithm can decide in time $O(n^2)$ whether a given planar graph has branch-width at most k for a given k and output an optimal decomposition in time $O(n^4)$. Gu and Tamaki [19] improved that result to construct an $O(n^3)$ -time algorithm to output an optimal carving-decomposition or an optimal branch-decomposition of n -vertex planar graphs.

Testing Branch-Width at most k for Fixed k

As we discussed above, we cannot hope to have a polynomial-time algorithm to test whether branch-width is at most k for an input k . However, if we fix k as a constant, then the situation is different. Oum and Seymour [20] proved that for any fixed constant k , one can answer whether the branch-width is at most k in time $O(|E|^{8k+c})$ where c only depends on $f(\emptyset)$. Moreover, one can construct a branch-decomposition of width at most k in time $O(|E|^{8k+c+3})$.

For many applications on fixed-parameter tractable algorithms, it is desirable to have an algorithm which runs in time $O(g(k)n^c)$ for some function g and a constant c independent of k . Such an algorithm is called a *fixed-parameter tractable* algorithm with parameter k . It is still unknown whether there is a fixed-parameter tractable algorithm to decide whether branch-width of f is at most k when f is an integer-valued symmetric submodular function given as an oracle.

Fortunately, fixed-parameter tractable algorithms are known for most interesting classes of integer-valued symmetric submodular functions. Bodlaender and Thilikos [21,22] constructed a linear-time algorithm to test whether branch-width of an input graph is at most k for fixed k . Thilikos *et al.* [23] constructed a linear-time algorithm to decide whether carving-width is at most k for fixed k . Hliněný and Oum [24] showed that there exists a cubic-time algorithm to decide whether rank-width of a graph is at most k for fixed k . Their algorithm also works for branch-width of matroids represented over a fixed finite field. All of these algorithms mentioned above can output the corresponding branch-decomposition as well.

Fixed-Parameter Tractable Approximation Algorithms

For applications on fixed-parameter tractable algorithms with the branch-width as a parameter, we often need a fixed-parameter tractable algorithm to construct a branch-decomposition of small width in order to use the dynamic programming approach. So far, we do not know the existence of a fixed-parameter tractable algorithm that can output a branch-decomposition of width at most k if such a branch-decomposition exists, for an integer-valued symmetric submodular function given by an oracle. As we discussed above, the best algorithm known runs in time $O(|E|^{8k+c+3})$.

As a workaround, Oum and Seymour [2] constructed the following algorithm: for each fixed k , it runs in time $O(|E|^7 \log |E|)$ to either output a branch-decomposition of width at most $3k + c'$ or confirm that the branch-width is larger than k , where c' only depends on $f(\emptyset)$ and $\max\{f(\{e\}) : e \in E\}$. (In fact, the article [2] only discusses the case when $f(\emptyset) = 0$ and $f(\{e\}) \leq 1$ for all $e \in E$. But its argument can be modified to accommodate the case when there is an element $e \in E$ such that $f(\{e\}) - f(\emptyset) > 1$.) This allows us to construct a branch-decomposition of small width from the given adjacency list of a graph, and this branch-decomposition can be used to solve other algorithmic problems by the dynamic programming technique.

There are similar algorithms for branch-width of matroids represented over a finite field [25].

Heuristics

Cook and Seymour [26,27] gave a heuristic algorithm to produce branch-decompositions of graphs and used it in their work on the ring-routing problem and the traveling salesman problem. Hicks [28] also found another branch-width heuristic that was comparable to the heuristic of Cook and Seymour. Recently, Ma and Hicks [29] found two heuristics to derive near-optimal branch-decompositions of linear matroids; one of the heuristics uses classification techniques and the other one is similar to the heuristics for graphs which use flow algorithms.

ALGORITHMIC APPLICATIONS

Branch-Width of Graphs

There are many graph-theoretic algorithmic problems that are shown to be polynomial-time solvable on the class of graphs of bounded branch-width. Many of them actually run their algorithms based on tree-width. We refer to the section on tree-width for such applications.

Branch-width is used to design exact subexponential-time algorithms or efficient parameterized algorithms on the class of planar graphs or the class of graphs with no fixed minor [30–35].

Branch-Width of Matroids

Hliněný [36] extended Courcelle's theorem on graphs of bounded tree-width or branch-width to matroids represented over a fixed finite field. Namely, for a fixed finite field F and a given monadic second-order formula φ on matroids, one can test whether an input F -represented matroid of bounded branch-width satisfies φ in time polynomial in the size of the matroid. The requirement that the matroid has to be represented over a finite field cannot be relaxed unless $\text{NP}=\text{P}$, shown by Hliněný [37].

Hliněný [38] also found a fixed-parameter tractable algorithm to evaluate the Tutte polynomial of an input matroid represented over a fixed finite field of bounded branch-width.

Rank-Width of Graphs

Rank-width is a sibling of better known clique-width, that is a kind of a generalization of tree-width. Oum and Seymour [2] proved not only that for every class of graphs, rank-width is bounded if and only if clique-width is bounded, but also that one can translate a rank-decomposition into a decomposition for clique-width and vice versa in polynomial time. It had been known that many algorithmic properties of tree-width could be generalized to graphs of bounded clique-width, even before rank-width was introduced and it is easy to see that all of such algorithmic results on graphs of bounded clique-width apply to rank-width.

Here is one of the most important theorems for graphs of bounded rank-width. Courcelle *et al.* [39] proved that there is a cubic-time algorithm to decide whether a fixed monadic second-order formula without edge-set quantification is satisfied by an input graph of bounded rank-width. As a corollary, many hard problems such as 3-colorability are solvable in a cubic time for graphs of bounded rank-width.

Practical Algorithms

Although theory indicates the fruitful potential of these algorithms, the number of practical algorithms in the literature is scant. Most notable is the work of Cook and Seymour [27], who produced the best known solutions for the 12 unsolved problems in TSPLIB95, a library of standard test instances for the traveling salesman problem [40]. Hicks presented a practical algorithm for general graph minor containment [41] and for constructing optimal branch decompositions [42]. One is also referred to the work of Christian [43].

Based on branch-width of matroids, Cunningham and Geelen [44] proposed a

pseudopolynomial-time algorithm to solve an integer programming problem $\max(c^T x : Ax = b, x \geq 0, x \in \mathbb{Z}^n)$, when A is nonnegative and the matroid represented by A has bounded branch-width. Their algorithm shows some hope to make branch-width much more useful for practical applications, as many problems are modeled as an integer programming algorithm.

BRAZILIAN SOCIETY OF OPERATIONAL RESEARCH

ANNIBAL PARRACHO SANT'ANNA
Escola de Engenharia,
Universidade Federal
Fluminense, Niterói, Rio de
Janeiro, Brazil

The Brazilian Society of Operational Research (SOBRAPO) was founded in 1969, after the completion of the First Symposium of Operational Research in 1968, held in the Aeronautics Technological Institute (ITA) in São José dos Campos-SP, by Oswaldo Fadigas Sources Torres, Ricardo Alberto Von Ellenrieder, Roberto Gomes da Costa, Ruy Braga Vianna, Alfredo Otto Brockmeyer, Mario Rosenthal, Ricardo Augusto France Leme, Ellery Gyro Sergio Barroso, Ramiro A. de Almeida Sobrinho, Jointly Rodolpho Teixeira, Carlos Sigfrido Mazza, Nelson Ortega da Cunha, Antonio Campos Salles Filho, Celso Pascoli Bottura, José Luiz Fabiani, Itiro Iida, Claus Warzhariet, Sergio Grinberg, Pedro Rodrigues Bueno Neto, Sergio Viana Domingues, and Grystz Israel.

Since then, SOBRAPO has been aggregating a large community of professionals in the area of operational research in Brazil, in the universities, in business, and in the public sector. Now the society has among their associates not only people but also institutions of these three sectors of activity.

In these four decades, SOBRAPO has had 16 presidents: Oswaldo Fadigas Fontes Torres (1969–1970), Roberto Gomes da Costa (1971–1972), Ricardo Alberto Von Ellenrieder (1973–1974), Nelson Maculan Filho (1975–1976), Ramiro de Araújo Sobrinho (1977–1978), Izaltino Camozzato (1979–1980), Roberto Dieguez Galvão (1981–1982), Newton Paciornik (1983–1984), Alberto Gabbay Canen (1985–1986), Rogério de Miranda Freire (1987–1988), Celso Cruz Carneiro Ribeiro (1989–1990), Paulo Roberto Oliveira (1991–1992), Reinaldo Castro Souza

(1993–1998), Luiz Flavio Autran Monteiro Gomes (1999–2002), Nélío Domingues Pizzolato (2003–2006), and Annibal Parracho Sant'Anna (2007–2010).

Affiliated to IFORS (International Federation of Operational Research Societies) and ALIO (Asociación Latino-Ibero-Americana de Investigación Operativa), SOBRAPO by its collaboration with international institutions and by directly publishing and enhancing expertise, maintains contact with the world in general, helping to disseminate, in conferences and journals, the scientific work of Brazilian researchers. Internally, SOBRAPO is a member society of the Brazilian Society for Scientific Enhancement (SBPC).

SOBRAPO publishes its own scientific periodicals, *Pesquisa Operacional* and *Pesquisa Operacional para o Desenvolvimento*. *Pesquisa Operacional* completes its third decade, now with English as its language. It offers three issues a year, with around ten refereed articles each. It is indexed in the International Abstracts in Operations Research, and is published on-line in SciELO since 2002. *Pesquisa Operacional para o Desenvolvimento* was created in 2009 to publish on-line texts in Portuguese and in Spanish.

The editor of *Pesquisa Operacional* for the past 10 years was Horacio Hideki Yanasse (Space Research National Institute – INPE). He was preceded by Roberto Dieguez Galvao. The Editorial Board included as associate editors, Andres Weintraub (Universidade do Chile), Antonio Galvão Novaes (Universidade Federal de Santa Catarina), Basílio de Bragança Pereira (Universidade Federal do Rio de Janeiro), Brian T. Boffey (University of Liverpool), Derek Bunn (London Business School), Geraldo Robson Mateus (Universidade Federal de Minas Gerais), Gerson Lachtermacher (Instituto Brasileiro de Mercado de Capitais), Gilbert Laporte (HEC Montreal), John Beasley (Imperial College of Science, Technology and Medicine), José Mario Martinez (Universidade Estadual de

Campinas), Marcos Nereu Arenales (Universidade de São Paulo em São Carlos), Maurício G. C. Resende (AT&T Labs—Research), Nair Maria M. de Abreu (Universidade Federal do Rio de Janeiro), Nelson Maculan Filho (Universidade Federal do Rio de Janeiro), Paulo Renato de Moraes (Universidade do Vale do Paraíba), Reinaldo Castro Souza (Pontifícia Universidade Católica do Rio de Janeiro), Reinaldo Morabito (Universidade Federal de São Carlos), and Vinícius Amaral Armentano (Universidade Estadual de Campinas).

Among the topics more frequently covered in the more recent volumes of *Pesquisa Operacional* are container loading problems, cutting and packing, efficiency evaluation, facilities location, economic forecasting, genetic algorithms, graphs characterization, GRASP procedures, interior point methods, multicriteria methods, quality control, and reliability assessment.

In addition, SOBRAPO hosts annual congresses, the Brazilian Symposia on Operational Research (SBPO), with an average of 500 participants and more than 200 communications each year. The articles submitted are accepted only after careful refereeing and, if presented at the symposium, are published in the *Annals of SBPO*. SBPO calls for papers in theoretical research fields such as mathematical programming, combinatorial optimization, metaheuristics, simulation, statistics, graph theory, multicriteria decision analysis, and data envelopment analysis. From the point of view of applications, the communications include applications to education, electric energy, finance, health, information, logistics, military operations, networks, oil and gas, quality control, production administration, and transportation, among other sectors.

In 2008, to celebrate 40 years of SBPO, SOBRAPO offered prizes for the best papers presented at the symposium, in three distinct areas: optimization, decision, and management. The prize for decision was awarded to the paper “New product development projects evaluation under time uncertainty,” by Leonardo Santiago (Universidade Federal de Minas Gerais) and Thiago Silva (Universidade Federal de Minas Gerais). The prize for management was shared between the papers

“A study on the universal access to vaccines in Brazil,” by Fabio Dias Fagundes (Universidade Federal do Rio de Janeiro), João Lauro Dorneles Facó (Universidade Federal do Rio de Janeiro), Roberto Medronho (Universidade Federal do Rio de Janeiro), Adilson Xavier (Universidade Federal do Rio de Janeiro), and Leandro Xavier (Instituto Oswaldo Cruz) and “Monitoring bivariate processes,” by Antonio Fernando Branco Costa (Universidade Estadual Paulista), Fernando Antonio Elias Claro (Universidade Estadual Paulista), and Marcela Aparecida Guerreiro Machado (Universidade Estadual Paulista). The prize for optimization was also awarded to two papers: “An improved algorithm for the generalized quadratic assignment problem,” by Artur Alves Pessoa (Universidade Federal Fluminense), Monique Guignard (University of Pennsylvania), Peter Hahn (University of Pennsylvania), and Yi-Rong Zhu (University of Pennsylvania) and “A branch-and-cut SDP-based algorithm for minimum sum-of-squares clustering,” by Daniel Aloise (École Polytechnique de Montreal) and Pierre Hansen (GERAD).

Other articles selected for the final round were “A column generation approach for shared protection schemes in WDM mesh networks,” by Brigitte Jaumard (Concordia University) and Caroline Rocha (Université de Montréal); “A compact code for k -trees,” by Lilian Markenzon (Universidade Federal do Rio de Janeiro), Paulo Renato da Costa Pereira (Instituto Militar de Engenharia), and Oswaldo Vernet (Universidade Federal do Rio de Janeiro); “A fuzzy cultural immune system for economic load dispatch with non-smooth cost function,” by Myriam Delgado (Universidade Federal Tecnológica do Paraná), Carolina de Almeida (Universidade Estadual do Centro-Oeste), Ricardo Gonçalves (Universidade Estadual do Centro-Oeste/Universidade Federal Tecnológica do Paraná), Josiel Kuk (Universidade Federal Tecnológica do Paraná), and Nátalli Rodrigues (Universidade Estadual do Centro-Oeste); “An efficient iterated local search algorithm for the vehicle routing problem with simultaneous pickup and delivery,” by Lucídio Cabral (Universidade Federal da Paraíba), Luiz Satoru

Ochi (Universidade Federal Fluminense), Anand Subramanian (Universidade Federal Fluminense); “Applying a new approach methodology with ZAPROS,” by Plácido Rogério Pinheiro (Universidade de Fortaleza) and Isabelle Tamanini (Universidade de Fortaleza); “Decision Analysis for the exploration of gas reserves: merging TODIM and THOR,” by Luiz Flavio Autran Monteiro Gomes (Ibmec-RJ), Carlos Francisco Simões Gomes (Ibmec-RJ) and Francisco Maranhão (OGX Oil & Gas); “Decision theory with multiple criteria: an application of ELECTRE IV and TODIM to SEBRAE/RJ,” by Luis Alberto Duncan Rangel (Universidade Federal Fluminense, Rogério Amadel Moreira (Universidade Federal Fluminense) and Luiz Flavio Autran Monteiro Gomes (Ibmec-RJ); “Design of robust financial products using system dynamics and multi-objective genetic algorithms,” by Eder Abensur (Universidade Federal do ABC); “Safe sex and the spread of HIV,” by Valter de Senna (SENAI-CIMATEC), Hernane Pereira (SENAI-CIMATEC/Universidade Estadual de Feira de Santana), and Israel Vieira (University of Southampton); and “Tests and preventive maintenance scheduling optimization for aging systems modeled by GRP,” by Vinicius Damaso (Centro Tecnológico do Exército) and Pauli Garcia (Universidade Federal Fluminense).

Every year, SOBRAPO also awards a prize for the student or group of students submitting the best Scientific Initiation Work Report. In 2009, five reports were selected for the prize: “Intensive local search: a new meta-heuristics for restricted continuous global optimization,” submitted by Wendel Melo (Universidade Federal do Rio de Janeiro); “MDM-GRASP: a hybrid and adaptive meta-heuristic,” submitted by Richard Fuchshuber (Universidade Federal Fluminense); “Meta-heuristics with local search do the problem of just-in-time job-shop scheduling,” submitted

by Rodolfo Araujo (Universidade Federal de Viçosa); “Optimizing trajectories of nonholonomic vehicles,” submitted by André Cesar de Souza Medeiros (Universidade Federal de Minas Gerais); and “PLIM Model with linear power flow for heat exchange in electric energy distribution networks,” submitted by Lucas El G. de Lara (Universidade Federal Tecnológica do Paraná).

In the same way, every year, small-term courses are offered for the participants of SBPO. In 2009, these courses focused on economics of the health market, by Sebastian Flourier (Universidade Federal da Bahia); fractionary graph theory, by Samuel Jurkiewicz (Universidade Federal do Rio de Janeiro); multicriteria decision aid for the public sector, by Carlos Bana e Costa (Instituto Superior Técnico of Lisbon, Portugal); and optimization in management and scheduling of sports events, by Celso Carneiro Ribeiro (Universidade Federal Fluminense).

SOBRAPO also contributed toward the International Conferences on Operations Research for Development, which were held twice in Brazil, in 1996 and 2007. SOBRAPO has also participated in the organization of the Symposia of Operation Research of the Marine, held in CASNAV and CASOP, research units of the Brazilian Marine.

The society also has among its goals the development of regional initiatives around the country. Therefore, regional meetings have been held on operational research in the Northeast, in the cities of Recife-PE and Natal-PE, and in the South, in the city of Foz do Iguaçu-PR and Porto Alegre-RS. From the efforts of the SOBRAPO community, important enterprises in Brazil, like PETROBRAS and VALE, and companies of the electric energy sector have a tradition of maintaining strong research groups in operational research.

BROWNIAN MOTION AND QUEUEING APPLICATIONS

DAVID D. YAO
IEOR Department, Columbia
University, New York, New York

BASIC PROPERTIES

Let $\{B(t), t \geq 0\}$ denote the standard Brownian motion (BM). Let

$$dB(t) := B(t + dt) - B(t)$$

denote an increment of the BM, with $dt > 0$ being a time increment. Let $N(\mu, \sigma^2)$ denote a normal distribution with mean μ and variance σ^2 ; let Z denote the random variable following the standard normal distribution $N(0, 1)$.

Here are some of the key properties of BM. It is a Markov process, with a continuous trajectory (sample path) over time, starting at $B(0) = 0$. It has independent and stationary increments; specifically, $dB(s)$ and $dB(t)$ are independent, for any $s + ds \leq t$, and $dB(t)$ follows a normal distribution $N(0, dt)$, which depends only on the length of the increment, but not on where it starts (hence, “shift invariant,” or stationary). Also note that it is the variance, not the standard deviation, that is proportional to the length of the increment.

Fix a time $t > 0$, and divide the interval $[0, t]$ into 2^n equal segments. Denote

$$\Delta_k(n) := B\left(\frac{k}{2^n}t\right) - B\left(\frac{k-1}{2^n}t\right).$$

Then, $\Delta_k(n)$, for $k = 1, \dots, 2^n$, are i.i.d. $N(0, t/2^n)$ random variables. The total variation (TV) and quadratic variation (QV) of the BM are defined as follows:

$$\begin{aligned} (\text{TV}) &:= \lim_{n \rightarrow \infty} \sum_{k=1}^{2^n} |\Delta_k(n)|, \\ (\text{QV}) &:= \lim_{n \rightarrow \infty} \sum_{k=1}^{2^n} [\Delta_k(n)]^2. \end{aligned} \quad (1)$$

It is known that

$$(\text{TV}) = \infty \quad \text{and} \quad (\text{QV}) = t.$$

A continuous function of time (such as what BM is) that has the above path properties—an infinite TV and a finite QV—implies that it must have an infinite number of ups and downs over any finite time interval, with the size of upward and downward movements being infinitesimally small. This essentially depicts what a BM path looks like over time.

That $(\text{QV}) = t$ also leads to the following property:

$$[dB(t)]^2 - dt = 0, \quad \text{as } dt \rightarrow 0. \quad (2)$$

Note that whereas $\mathbf{E}([dB(t)]^2) = dt$, we have,

$$\begin{aligned} \mathbf{Var}([dB(t)]^2) &= \mathbf{Var}(dt \cdot Z^2) \\ &= (dt)^2 \mathbf{Var}(Z^2) = 2(dt)^2. \end{aligned}$$

The relation in Equation (2) is, hence, intuitively appealing: the random variable $[dB(t)]^2$ has a variance that is a higher-order infinitesimal than its mean; thus, as $dt \rightarrow 0$, the random variable degenerates to a deterministic quantity (naturally, its mean dt).

Let $\mathcal{F} = \{\mathcal{F}_t, t \geq 0\}$ be an increasing family of sigma-fields (or, “filtration”); that is, $\mathcal{F}_s \subset \mathcal{F}_t$ for all $s > t$. Let $X = \{X(t), t \geq 0\}$ be a process that is adapted to $\mathcal{F}$, that is, $X(t) \in \mathcal{F}_t$ for every t . (Here, $X(t) \in \mathcal{F}_t$ is shorthand for $\{X(t) \leq x\} \in \mathcal{F}_t$ for any x .) X is called a *martingale* (w.r.t. $\mathcal{F}$) if $\mathbf{E}|X(t)| < \infty$ and $\mathbf{E}[X(t)|\mathcal{F}_s] = X(s)$ for all $s < t$.

Direct verification shows that both $\{B(t)\}$ and $\{\exp[\theta B(t) - \frac{1}{2}\theta^2 t]\}$ (where θ is a deterministic parameter) are martingales. (Here, $\mathcal{F}_t$ is taken to be the process history, the sigma-field associated with the BM up to t .) For instance, to verify the martingale property of the second process, we have, for

$s < t$,

$$\begin{aligned}\mathbf{E} \exp[\theta(B(t) - B(s)) | \mathcal{F}_s] &= \mathbf{E} \exp[\theta(B(t) - B(s))] \\ &= \exp\left[\theta\sqrt{t-s}Z\right] \\ &= \exp\left[\frac{1}{2}\theta^2(t-s)\right],\end{aligned}$$

where the first equality follows from the independent increment property, and the last equality follows from the known result (generating function of Z), $\mathbf{E}(e^{\theta Z}) = e^{\theta^2/2}$.

Taking expectation on both sides of $[X(t) | \mathcal{F}_s] = X(s)$ yields $\mathbf{E}X(t) = \mathbf{E}X(s)$ for any $t > s$; in particular, $\mathbf{E}X(t) = \mathbf{E}X(0)$ for any $t > 0$. That is, the martingale property implies the process has a constant mean over time. The so-called martingale optional stopping theorem extends (under certain technical conditions) this constant mean property to a stopping time, T : $\mathbf{E}X(T) = \mathbf{E}X(0)$. (Recall T is a stopping time if $\{T \leq t\} \in \mathcal{F}_t$ for any t .)

Let $X(t) = \mu t + \sigma B(t)$ be a BM with drift, where μ and $\sigma > 0$ are constant parameters. Consider the stopping time, $T = \inf\{t : X(t) \notin (-a, b)\}$, where a and b are positive constants. We want to derive p_b , the probability of $X(t)$ hitting b before $-a$. Applying the optional stopping theorem to the exponential martingale, we have

$$\begin{aligned}\mathbf{E}\left[\exp(\theta B(T) - \frac{1}{2}\theta^2 T)\right] &= 1 \\ \text{or} \\ \mathbf{E}\left[\exp\left(\frac{\theta}{\sigma}(X(T) - \mu T) - \frac{1}{2}\theta^2 T\right)\right] &= 1.\end{aligned}$$

Letting $\theta = -\frac{2\mu}{\sigma}$ yields $-\frac{\theta}{\sigma}\mu T - \frac{1}{2}\theta^2 T = 0$; hence, the second equation above reduces to

$$\begin{aligned}1 &= \mathbf{E}\left[\exp\left(-\frac{2\mu}{\sigma^2}X(T)\right)\right] \\ &= e^{2a\mu/\sigma^2}(1 - p_b) + e^{-2b\mu/\sigma^2}p_b.\end{aligned}$$

Thus,

$$p_b = \frac{e^{2a\mu/\sigma^2} - 1}{e^{2a\mu/\sigma^2} - e^{-2b\mu/\sigma^2}}. \quad (3)$$

Now, suppose $\mu < 0$, that is, the BM has a negative drift. Letting $a \rightarrow +\infty$ in Equation (3), we have $p_b = e^{-2b|\mu|/\sigma^2} < 1$; that is, the

probability of ever reaching b is less than 1. We can also write this as

$$\mathbf{P}\left[\sup_{0 \leq t < \infty} X(t) \geq b\right] = e^{-2b|\mu|/\sigma^2}, \quad \mu < 0, b \geq 0. \quad (4)$$

Note that $\sup_{0 \leq t < \infty} X(t)$ can be viewed as the limit, as $t \rightarrow \infty$, of $M(t) := \sup_{0 \leq s \leq t} X(s)$, the latter being nonnegative and nondecreasing. Hence, the maximum of a BM with a negative drift has a limiting distribution that is exponential with mean $\sigma^2/(2|\mu|)$.

DONSKER'S THEOREM

Consider the partial sums:

$$S_0 := 0, \quad S_k := \xi_1 + \cdots + \xi_k, \quad k = 1, 2, \dots, \quad (5)$$

where $\{\xi_i, i \geq 1\}$ is a sequence of i.i.d. non-negative random variables. Assume that $\mathbf{E}(\xi_1) = 1/\mu$ and $\mathbf{Var}(\xi_1) = \sigma^2$. Define for $t \geq 0$,

$$\begin{aligned}\alpha(t) &= S_{[t]} = \sum_{i=1}^{[t]} \xi_i, \\ \beta(t) &:= \sup\{s \geq 0 : \alpha(s) \leq t\}.\end{aligned} \quad (6)$$

Note in the context of renewal theory, with $\{\xi_i\}$ being the i.i.d. interevent times, $\alpha(t)$ is the $[t]$ -th arrival epoch and $\beta(t)$ is the associated counting process. From standard renewal theory, we know, as $n \rightarrow \infty$,

$$\begin{aligned}\bar{\alpha}^n(t) &:= \frac{1}{n}\alpha(nt) \rightarrow \frac{t}{\mu} := \bar{\alpha}(t), \\ \bar{\beta}^n(t) &:= \frac{1}{n}\beta(nt) \rightarrow \mu t := \bar{\beta}(t).\end{aligned} \quad (7)$$

Here, the mode of convergence is a.s. (almost surely, or with probability 1). More precisely, it is u.o.c., uniformly on all compact subsets of any time interval $[0, T]$, with a given T . The limits in Equation (7) can be viewed in the spirit of strong law of large numbers. For instance, for each given t , the average $\bar{X}^n(t)$ approaches its mean $\frac{t}{\mu}$. As the time

index t changes, the limit takes the form of a deterministic function of time. Hence, these limits are often referred to as a *functional strong law of large numbers* (FSLLN).

Note in Equation (7), a common scaling factor n is applied to both time and space. This resembles the “zoom-out” operation when we view a Google map, for instance, as the same scaling is applied to both the horizontal and vertical axes (of the map). The net effect of this scaling is that the random fluctuation around the mean disappears, resulting in a straight line. In order to preserve the random fluctuation, what we can do is to scale the space by a factor of a lesser order, $\sqrt{n}$, and still scale time by n . This way, the fluctuation around the mean is made more prominent. This is in the same spirit as how the central limit theorem refines the strong law of large numbers. The result under this scaling is the well-known *Donsker’s Theorem* [1], which is a functional central limit theorem (FCLT), with the (functional) limit being BM:

$$\begin{aligned}\hat{\alpha}^n(t) &:= \frac{1}{\sqrt{n}} \left[\alpha(nt) - \frac{nt}{\mu} \right] \\ &= \sqrt{n} [\bar{\alpha}^n(t) - \bar{\alpha}(t)] \\ &\Rightarrow \sigma B(t) := \hat{\alpha}(t),\end{aligned}\quad (8)$$

$$\begin{aligned}\hat{\beta}^n(t) &:= \frac{1}{\sqrt{n}} [\beta(nt) - \mu(nt)] \\ &= \sqrt{n} [\bar{\beta}^n(t) - \bar{\beta}(t)] \\ &\Rightarrow \mu^{3/2} \sigma B(t) := \hat{\beta}(t).\end{aligned}\quad (9)$$

The convergence mode above ($\Rightarrow$) is the so-called “weak convergence,” that is, the probability laws (distributions) of a sequence of processes converge to the probability law (distribution) of another process, the limit. In fact, the convergence is *joint*, that is, $(\hat{\alpha}^n, \hat{\beta}^n) \Rightarrow (\hat{\alpha}, \hat{\beta})$; and the limit of $\hat{\beta}^n$, $\hat{\beta}(t) = -\mu \hat{\alpha}(\mu t)$, follows from the limit of $\hat{\alpha}^n(t)$, based on the inverse functional relationship between α and β .

THE SKOROHOD PROBLEM

Let $x := \{x(t), t \geq 0\}$ be a process (deterministic or stochastic) that is right continuous with left limit (RCLL). Let y and z denote two other RCLL processes. Let $\mathcal{D}$ denote the functional space of all RCLL processes. (Note $\mathcal{D}$ includes all continuous processes as a subclass.) The Skorohod problem refers to the following: given the process x , find a pair (y, z) that satisfies

$$z = x + y \geq 0; \quad dy \geq 0, \quad y(0) = 0; \quad z dy = 0. \quad (10)$$

It can be directly verified that the solution to the above problem does exist and is unique; furthermore, with the solution denoted as $y = \Psi(x)$ and $z = \Phi(x)$, the mappings Ψ and Φ are both Lipschitz continuous. In fact, in the single-dimensional case (i.e., when x is a scalar process), the unique y and z can be explicitly expressed as follows:

$$\begin{aligned}y(t) &= \sup_{0 \leq s \leq t} [-x(s)]^+, \\ z(t) &= x(t) + \sup_{0 \leq s \leq t} [-x(s)]^+.\end{aligned}\quad (11)$$

When $x(t) := X(t) = \theta t + \sigma B(t)$, the BM with drift discussed earlier, with $\theta < 0$. Then, the solution to the above Skorohod problem is (note $X(0) = 0$)

$$\begin{aligned}y(t) &= \sup_{0 \leq s \leq t} \{-X(s)\} := Y(t), \\ z(t) &= \sup_{0 \leq s \leq t} \{X(t) - X(s)\} := Q(t).\end{aligned}\quad (12)$$

Note that

$$Q(t) \stackrel{d}{=} \sup_{0 \leq s \leq t} \{X(s)\} = M(t),$$

where $M(t)$ is the maximum BM discussed earlier (Eq. 4). $Q(t)$ is called a *reflected Brownian motion*, denoted by $\text{RBM}(\theta, \sigma^2)$. It has a stationary (or limiting) distribution, which is exponential, with mean $\sigma^2/(2|\theta|)$.

THE GI/GI/1 QUEUE

Now, consider a single-server queue, with a renewal arrival process and i.i.d. service times following a general distribution, the GI/GI/1 model. It is well known in queueing theory that this model does not have closed-form solutions to even the most basic performance measures such as steady-state mean queue length and average waiting time. Below, we first present the equations that govern the dynamics of this model, and then connect the equations via diffusion scaling to the Skorohod problem, which has an explicit solution, the RBM. This way, the GI/GI/1 model, under diffusion scaling, becomes very accessible analytically.

Let $A(t)$ and $S(t)$ be the renewal counting processes associated with i.i.d. interarrival times and i.i.d. service times. Let λ and μ be the arrival and service rates. Let $Q(t)$ be the queue-length process, that is, the total number of jobs in the systems at time t . Then, we have

$$\begin{aligned} Q(t) &= Q(0) + A(t) - S(D(t)), \quad \text{with} \\ D(t) &= \int_0^t \mathbf{1}\{Q(s) > 0\} ds. \end{aligned} \quad (13)$$

Here, $D(t)$ denotes the cumulative amount of time up to t when work is being depleted from the system (or equivalently, the server is busy). We can rewrite the above as

$$Q(t) = X(t) + Y(t), \quad (14)$$

with

$$\begin{aligned} X(t) &:= Q(0) + (\lambda - \mu)t + [A(t) - \lambda t] \\ &\quad - [S(D(t)) - \mu D(t)], \end{aligned} \quad (15)$$

$$Y(t) := \mu[t - D(t)]. \quad (16)$$

Furthermore, the following relations must hold: for all $t \geq 0$,

$$\begin{aligned} Q(t) &\geq 0; \quad dY(t) \geq 0, \quad Y(0) = 0; \\ Q(t) dY(t) &= 0. \end{aligned} \quad (17)$$

Note $Y(t)$ is the cumulative unused service capacity (service rate times idle time) up to t .

Hence, it must be nondecreasing ($dY(t) \geq 0$). Furthermore, $Q(t) dY(t) = 0$ means that the server must not be idling while the queue length is positive. Comparing the queueing dynamics in Equations (14) and (17) against Equation (10), we conclude that the former too constitute a Skorohod problem. In this case, however, the solution form in Equation (12) is not particularly helpful, as X is not quite a primitive process (input data), as it involves Q via D . Nevertheless, it turns out that a sequence of scaled queueing processes will converge to a limit that is characterized by the Skorohod problem, and with an explicit solution.

To illustrate, we first need the following result. Let $\{\theta_n, n \geq 1\}$ be a sequence of real values and $\{x_n, n \geq 1\}$ be a sequence in $\mathcal{D}$ with $x_n(0) \geq 0$. Let

$$\begin{aligned} y_n(t) &= \sup_{0 \leq u \leq t} [-x_n(u) - \theta_n u]^+, \\ z_n(t) &= x_n(t) + \theta_n t + y_n(t). \end{aligned} \quad (18)$$

Suppose that as $n \rightarrow \infty$, we have $\theta_n \rightarrow \theta < \infty$ and $x_n \rightarrow x$ u.o.c., with the limit $x := \{x(t)\}$ being a *continuous* function. Then, $(y_n, z_n) \rightarrow (y, z)$ u.o.c. as $n \rightarrow \infty$, where

$$\begin{aligned} y(t) &= \sup_{0 \leq u \leq t} [-x(u) - \theta u], \\ z(t) &= x(t) + \theta t + y(t). \end{aligned} \quad (19)$$

THE DIFFUSION LIMIT

Continue with the GI/GI/1 model introduced above. Applying fluid scaling to the primitives, the arrival and service counting processes, we assume the following limits exist as $n \rightarrow \infty$:

$$\begin{aligned} \bar{A}^n(t) &= \frac{1}{n} A(nt) \rightarrow \lambda t, \\ \bar{S}^n(t) &= \frac{1}{n} S(nt) \rightarrow \mu t. \end{aligned}$$

Assume in addition that $\bar{Q}^n(0) := \frac{1}{n} Q^n(0) \rightarrow \bar{Q}(0)$ as $n \rightarrow \infty$. Then, applying the same fluid scaling to Equation (15), and using the same

“bar” notation as in $\bar{A}^n(t)$ and $\bar{B}^n(t)$ above to all the processes concerned, we have

$$\begin{aligned}\bar{X}^n(t) &= \bar{Q}^n(0) + (\lambda - \mu)t + [\bar{A}^n(t) - \lambda t] \\ &\quad - [\bar{S}^n(\bar{D}^n(t)) - \mu \bar{D}^n(t)] \\ &\rightarrow \bar{Q}(0) + (\lambda - \mu)t := \bar{X}(t).\end{aligned}$$

Note here $\bar{S}^n(\bar{D}^n(t)) - \mu \bar{D}^n(t) = \frac{1}{n}[S(D(nt)) - \mu D(nt)] \rightarrow 0$, since

$$\begin{aligned}\frac{1}{nt} |S(D(nt)) - \mu D(nt)| &= \left| \frac{S(D(nt))}{D(nt)} - \mu \right| \\ \cdot \frac{D(nt)}{nt} &\leq \left| \frac{S(D(nt))}{D(nt)} - \mu \right| \rightarrow 0,\end{aligned}$$

where the inequality follows from $0 \leq D(nt) \leq nt$, and the limit follows from SLLN, taking into account that $D(nt) \rightarrow \infty$ as $n \rightarrow \infty$.

Consequently, we have

$$\begin{aligned}\bar{Y}(t) &= [-\bar{Q}(0) - (\lambda - \mu)t]^+, \\ \bar{Q}(t) &= [\bar{Q}(0) + (\lambda - \mu)t]^+, \end{aligned}$$

taking into account $\bar{Y}(t) = \sup_{0 \leq s \leq t} [-\bar{X}(s)]^+ = [-\bar{X}(t)]^+$. We also have $\bar{D}^n(t) \rightarrow \bar{D}(t) = t - \frac{1}{\mu} \bar{Y}(t)$.

Under diffusion scaling, the arrival and service counting processes converge to BM (via Donsker’s Theorem) as follows:

$$\begin{aligned}\hat{A}^n(t) &= \frac{A(nt) - \lambda nt}{\sqrt{n}} = \sqrt{n} [\bar{A}^n(t) - \lambda t] \\ &\Rightarrow \sqrt{\lambda} c_a B_1(t) := \hat{A}(t), \\ \hat{S}^n(t) &= \frac{S(nt) - \mu nt}{\sqrt{n}} = \sqrt{n} [\bar{S}^n(t) - \mu t] \\ &\Rightarrow \sqrt{\mu} c_s B_2(t) := \hat{S}(t),\end{aligned}$$

where B_1 and B_2 are two independent standard BMs, and $c_a := \lambda \sigma_a$ and $c_s := \mu \sigma_a$ are the coefficients of variation of the interarrival times and the service times, respectively.

Applying diffusion scaling to the queue-length process, we have

$$\hat{Q}^n(t) = \hat{X}^n(t) + \hat{Y}^n(t), \quad (20)$$

where (assuming $\hat{Q}^n(0) = 0$ for simplicity)

$$\hat{X}^n(t) = (\lambda - \mu)\sqrt{nt} + \hat{A}^n(t) - \hat{S}^n(\bar{D}^n(t)), \quad (21)$$

and $\hat{Y}^n(t) = \sqrt{n}\mu[t - \bar{D}^n(t)]$. Note the drift term in $\hat{X}^n(t)$ has a factor of $\sqrt{n}$. Consequently, $\hat{X}^n \rightarrow +\infty$ (and $\hat{Q}^n \rightarrow +\infty$) if $\lambda > \mu$, whereas $\hat{X}^n \rightarrow -\infty$ (and $\hat{Q}^n \rightarrow 0$) if $\lambda < \mu$. Hence, a nontrivial limit requires $\lambda = \mu$, the so-called *heavy traffic condition*. In this case, following the fluid limit derived above, we have $\bar{D}^n(t) \rightarrow \bar{D}(t) = t$. Hence, $\hat{X}^n(t) \Rightarrow \hat{A}(t) - \hat{S}(t)$.

A refinement is achieved by considering a sequence of queues indexed by n . Let λ_n and μ_n be the arrival rate and the service rate, respectively, for the n th queue. Assume the following:

$$\begin{aligned}\sqrt{n}[\lambda_n - \mu_n] &\rightarrow \theta < 0, \quad \text{and} \\ \lambda_n &\rightarrow \lambda, \quad \mu_n \rightarrow \mu.\end{aligned} \quad (22)$$

The diffusion-scaled arrival and service processes above require only minor modifications as follows:

$$\begin{aligned}\hat{A}^n(t) &= \frac{A^n(nt) - \lambda_n nt}{\sqrt{n}} = \sqrt{n} [\bar{A}^n(t) - \lambda_n t] \\ &\Rightarrow \sqrt{\lambda} c_a B_1(t) := \hat{A}(t), \\ \hat{S}^n(t) &= \frac{S^n(nt) - \mu_n nt}{\sqrt{n}} = \sqrt{n} [\bar{S}^n(t) - \mu_n t] \\ &\Rightarrow \sqrt{\mu} c_s B_2(t) := \hat{S}(t).\end{aligned}$$

That is, the diffusion scaling is now applied to (the primitive processes of) the sequence of queues, and so is the fluid scaling $\bar{A}^n(t) = \frac{1}{n}A^n(nt) \rightarrow \lambda t$ and $\bar{S}^n(t) = \frac{1}{n}S^n(nt) \rightarrow \mu t$.

Consequently, Equation (21) becomes

$$\begin{aligned}\hat{X}^n(t) &= (\lambda_n - \mu_n)\sqrt{nt} + \hat{A}^n(t) - \hat{S}^n(\bar{D}^n(t)) \\ &\Rightarrow \theta t + \hat{A}(t) - \hat{S}(t).\end{aligned} \quad (23)$$

Therefore, in this case, $\hat{Q}^n(t) \Rightarrow \text{RBM}(\theta, \lambda c_a^2 + \mu c_s^2)$.

Note that the assumed conditions in Equation (22) imply $\lambda = \mu$; hence, the heavy traffic condition remains in force. However, the above enables us to view the GI/GI/1 queue in question as a member of the

sequence of queues under scaling, so that we can *approximate* it, when $\lambda \neq \mu$, by the $\text{RBM}(\theta, \lambda c_a^2 + \mu c_s^2)$, with $\theta = \lambda - \mu$. When $\lambda < \mu$ (or, $\theta < 0$), we know the queue has a stationary distribution, which can also be approximated by the stationary distribution of the RBM, which we know is exponential with a mean $(\lambda c_a^2 + \mu c_s^2)/(2|\theta|)$.

BIBLIOGRAPHICAL NOTES

Introductory materials for BM can be found in Karlin and Taylor [2] (Chapter 8) and in Ross [3] (Chapter 8). Harrison [4] covers both the basic theory and essential applications of BM in inventory and queueing systems. Ref. 1 is a standard reference on weak convergence; also refer to Ref. 5 for a survey of weak convergence in the $\mathcal{D}$ space and related diffusion approximations.

Queueing systems that have closed-form analytical solutions are limited to models that have Poisson arrivals and/or i.i.d. exponential service times, and in most cases, it is also limited to a single server. Once outside the Markov chain (or embedded Markov chain) setting, the most effective analytical approach is asymptotic analysis, via fluid and diffusion scalings.

Kingman [6–8] pioneered the diffusion approximation of single-server queues; also refer to Borovkov [9]. Iglehart and Whitt [10,11] developed the heavy-traffic theory for many-server queues. Halfin and Whitt [12] applied a different kind of diffusion scaling to the many-server queue model with exponential service times, leading to a limiting regime that is a combination of BM and Orstein–Uhlenbeck process.

This article is adapted from Chapters 5 and 6 of Ref. 13. Later chapters of the book discuss applications of Brownian models to networks of queues, as opposed to the stand-alone (i.e., single-node) queue model presented here. In this regard, Refs 14 and 15 are the first works that extend the heavy-traffic theory to single-class queueing networks (generalized Jackson networks). Harrison [16] presents an overview of the Brownian models of general stochastic processing networks with multiclass jobs

and operating under various routing and service mechanisms. Dai [17] demonstrates that the fluid model is a critical tool in characterizing the stability of multiclass networks. Williams [18] establishes the general theory of reflection mapping, or Skorohod problem in higher dimension, which is the key to establish limiting regimes for networks. Reference 19 is one example, among many others in the literature, that illustrates the advantage of asymptotic analysis not only in performance evaluation but also in identifying asymptotically optimal scheduling policies (i.e., optimal under diffusion scaling). More recent studies by Kang *et al.* [20] and Ye and Yao [21] provide further examples of the power of Brownian models in handling certain new features in contemporary stochastic networks, such as resource controls involved in Internet protocols.

BUSINESS PROCESS OUTSOURCING

ANDY A. TSAY

OMIS Department, Leavey School of
Business, Santa Clara University,
Santa Clara, California

This article describes a practice that is implicitly considered by every individual or organization every day, is central to the strategic business models of many modern firms, and has even become a mainstay of lay conversation (albeit with sometimes incorrect usage). We first introduce terminology necessary to explain “Business Process Outsourcing” (BPO) in general (henceforth, simply “Outsourcing”), discuss the decision process for choosing whether or not to outsource an activity, and then summarize best practices for managing the service providers. We conclude with a comment about ORMS research on outsourcing. This article is intended to serve as a tutorial, and will not provide a comprehensive review of the research literature. A follow-up article in this encyclopedia (see *Supply Chain Outsourcing*) extends this BPO dialogue to the outsourcing of manufacturing/production/assembly, procurement/sourcing, logistics, and product design/development.

TERMINOLOGY

The Oxford English Dictionary (OED) offers this definition:

Outsource: to obtain (goods, a service, etc.) by contract from an outside source; to contract (work) out.

The OED cites as the term’s earliest appearance in print a 1979 item in the *Journal of the Royal Society of Arts*, in the sentence “We are so short of professional engineers in the motor industry that we are having to outsource design work to Germany.”

Some interpret the term to specifically connote the act of shifting an internal activity to an outside party. However, the above definition, which we follow in this article, does not stipulate where the activity might have been formerly performed. For instance, firms are correctly said to be outsourcing their manufacturing even if they opted from day one to focus solely on designing and marketing their products, so that at no point ever possessed any manufacturing capabilities [1].

The antonym of “outsource” is “insource,” which thus means to perform an activity internally. Likewise this does not require that the activity was ever previously outsourced. The OED shows both words to have begun appearing in print around the same time.

The act of outsourcing involves two main participants, neither of which has a prevailing name. Some possibilities for the one receiving the good or service are “buyer,” “client,” “service recipient,” or “outsourcer.” The providing party can be “supplier,” “vendor,” “service provider,” or “outsourcee.” Of these, the mainstream usages of “buyer,” “supplier,” and “vendor” slightly hint at the selling of packaged product rather than services, although nothing in the formal definitions specifies this. “Outsourcer” and “outsourcee” draw specific attention to the nature of the relationship. The latter is not commonly used, perhaps since it could be misunderstood to be the internal employee laid off when his/her function was outsourced. To add to the confusion, the firm on the selling side is occasionally labeled as an “outsourcer.” In this article, we will generally identify these two parties as the “outsourcing party” and “service provider,” since these are sufficiently neutral and clear. The latter also has support in the labels applied to such emerging specialist categories as “Procurement Service Providers” (PSP) or “Manufacturing Service Providers” (MSP). This article will use language descriptive of outsourcing performed by organizations for business purposes, although most of

the concepts will be just as relevant when individuals outsource or when the objectives are noncommercial.

Besides naming the actors and their actions, we also need vocabulary to identify the constellation of linked partners that results from extensive outsourcing. A nonexhaustive list includes “virtual supply chain,” “virtual value chain,” “virtual integration,” and “extended enterprise.” The first two differ in the subtle distinction between a supply chain, which describes the parties along a physical path of flow, and a value chain, which highlights the activities performed but does not necessarily map to a physical or chronological sequence or have a crisp division of labor. “Virtual integration” forms a dyad with “vertical integration.” “Extended enterprise” may be the least explicitly suggestive of outsourcing. This simply encompasses the full ecosystem of parties needed to provide a product or service, but does not allude to a consolidated alternative. Terms of this ilk are disparaged by some as business jargon, and those mentioned here may very well be *passé* by the time this article appears.

Two additional keywords merit elaboration, since they arise in nearly every discussion of outsourcing. They are “offshoring,” which is a distinct but sometimes related business action, and “core competence” (CC), which is central to one of the popular rationales for outsourcing.

Offshoring

“Outsourcing” is sometimes misused in place of “offshoring,” especially in political commentaries that unfairly disparage the former for endangering the jobs of hard-working local citizens. In fact, while offshoring moves work to another country, outsourcing only shifts tasks to another organization and need not entail a location change at all. The employees of service providers sometimes work alongside the client’s internal staff, wearing the same uniforms, checking email on the same servers, and living and paying taxes in the same communities. Offshoring typically seeks to leverage an internationally based workforce that is cheaper and/or better suited for a task, but may also reduce

taxes and duties, and offer proximity to end-customers and input suppliers.

In this age of global free trade and increasingly complete marketplaces for virtually every imaginable product or service, a firm can outsource without going offshore, and vice versa. Nearly every multinational corporation outsources some activities to domestic vendors and insources other activities via wholly owned facilities that may be spread across many countries. For instance, GM outsources aspects of production to vendors in the United States, as well as Canada and Mexico. Meanwhile, Toyota and BMW own production facilities in the United States. Even in the highly outsourced mobile phone sector, the majority of Nokia’s production occurs at the Finnish firm’s own factories around the world (including in Finland and the United States) [2]. In 2007, Wipro, an India-based leading provider of outsourced IT services, announced plans to open four software development centers in the United States. Through this, Wipro will offshore without outsourcing, while Wipro’s American clients will be outsourcing without offshoring.

Outsourcing and offshoring do sometimes occur simultaneously, for which the unambiguous label is “offshore outsourcing.” This strategy is motivated by a belief that the shortest path to the benefits offered by an offshore solution is to outsource to a service provider with expertise and resources in the appropriate geographies. Everything from low end manual labor to high end knowledge work is a candidate for offshore outsourcing these days.

Should outsourcing take activities offshore, the risk factors and challenges detailed in the section titled, “Advantages and Disadvantages of Outsourcing” will only be intensified by any cultural or language barriers, differences in legal codes and enforcement practices (especially vis-à-vis the protection of intellectual property), or misalignment in attitudes toward environmental and human rights issues. And geographic distance only complicates the monitoring needed to assure that a service provider’s actions are true to its customer’s intentions. These issues are particularly

salient when offshore outsourcing involves emerging economies.

Core Competence

Prahalad and Hamel popularized the notion of CC in a 1990 *Harvard Business Review* article [3]. Their CCs, of which most firms will have not more than five or six, are defined by three key attributes:

- They provide potential access to a wide variety of markets.
- They make a significant contribution to perceived customer benefits of the end product.
- They are difficult for competitors to imitate.

The basic message in that article is that an organization can maximize its competitive advantage by identifying its CCs and organizing activities around them. These authors deem the outsourcing of CCs to be a strategic error of the highest order, but make no pronouncement about how to handle the noncore activities.

Quinn and Hilmer [4] articulate the connection between CCs and outsourcing that has become central to the modern business zeitgeist, paraphraseable as “Focus on your CCs, and outsource everything else.” By their definition, CCs are

- skill or knowledge sets, not products (which can be reverse-engineered) or functions (since CCs tend to cut across traditional functions, e.g., production, engineering, sales, finance);
- flexible, long-term platforms that are capable of adaptation or evolution;
- limited in number to perhaps two or three (more than one, but fewer than five);
- unique sources of leverage in the value chain;
- areas where the company can dominate;
- elements important to customers in the long run;
- embedded in the organization’s systems (rather than dependent upon key individuals).

In the eyes of both sets of authors, CCs are *not* “things we do very well or very often,” but instead *are* “things that are strategically important.” These are rarely confined to individual product departments or functional areas. Given this, current usage has become somewhat of a perversion of what these articles expound, as evidenced by commonly heard statements such as “We outsource manufacturing because design and marketing are our CCs.” Perhaps this can be reconciled through the way the term’s meaning has evolved since the early 1990s, which is captured in far too many articles to document here.

A semantic matter is whether the second C in the term should stand for “competence” or “competency.” The OED views these as interchangeable. Neither version of CC appears in the OED as of 2008. Google searches on November 2, 2008 provided the following numbers of results:

“core competence” and “core competences”:
 ~ 463,000 and ~ 122,000, respectively
 “core competency” and “core competencies”:
 ~ 754,000 and ~ 1,980,000, respectively

Hence, both terms are commonplace, but “competency” seems more prevalent.

ADVANTAGES AND DISADVANTAGES OF OUTSOURCING

Even if the term “outsourcing” might be fairly new, the actual practice is not. Because no organization can do everything itself, each one must choose a division of labor in every endeavor, defining its own roles and ceding any remaining duties to other parties. The key questions are which activities and to what extent.

Proponents commonly emphasize the outsourcing party’s resulting ability to focus on those activities deemed CCs for their strategic significance, as noted earlier. Converting some fixed costs to variable costs can increase financial and operational flexibility, and improve return on assets. Tax benefits may also accrue on moving certain activities to outside parties. Outsource service providers ostensibly enjoy superior cost

structures due to specialization and scale economies, and lower risk because they can balance the peaks in some customers' needs with valleys in others'. Some argue that outsiders provide better service with fewer headaches than would a company's own employees, as outsiders are easier to terminate and therefore ought to be more willing to please. But outsourcing need not be about replicating an existing function at lower cost or with improved quality. An outside party may offer transformative capabilities that are unavailable any other way [4].

Through outsourcing, firms risk eroding critical capabilities, institutional and tacit knowledge, and long-term relationships. Communication and coordination among internal and outsourced functions can be difficult and costly. Dependence leaves firms susceptible to service providers' underperformance, holding hostage of critical assets (like scarce parts or custom tooling), using their clients' product or process knowledge to benefit the firms' competitors, or even themselves becoming competitors. Outsourcing complicates decision making as power is distributed across a constellation of independently controlled firms whose relationships are shorter-term and more transactional. In many cases, the outcome has been disappointing [5–9].

Some of these difficulties of outsourcing result from the complexity, fragmented decision making, and broken information flows that come from decentralizing, which can be countered by process redesign and enhancement of information technologies. Others, however, reflect deliberate actions by service providers that are not in their clients' best interests. This possibility exists because of limitations in the client's ability to dictate and monitor the provider's actions (which are only exacerbated by any geographic or cultural separation). All this is particularly baffling for organizations whose institutional knowledge of the intricacies of the outsourced activity have been lost over time, or never existed in the first place [10].

Many processes conducted in-house also suffer from some variant of these challenges, but at least these play out under the auspices of the company's own internal checks and

balances. However, many companies equate outsourcing with reductions in resource and staff requirements, and fail to recognize that investments in business controls must actually increase to address the new risks. For some activities, properly overseeing the service provider may require such intimate involvement that the firm may be better off not outsourcing.

Many of the aforementioned costs and risks are manifestations of what economists classify as "transactions costs" (e.g., costs of search, contracting, negotiating, monitoring, and dealing with changes/disagreements), which are often invoked as a determinant of an industry's extent of vertical integration in the literature termed *transactions costs economics* (TCE) [11–13]. Constructs from Principal Agent (aka Agency) Theory, which focuses on relationships in which one party (the principal) delegates work to another (the agent), have been used to analyze these types of transactions costs. This framework highlights the "moral hazard" inherent in any relationship in which the principal's goals conflict with the agent's goals, and the principal has difficulty verifying the agent's actions (i.e., incomplete information).

INSOURCE-VERSUS-OUTSOURCE DECISION FRAMEWORKS

Defining which activities a firm should perform is among the most fundamental and profound of management duties, with consequences felt in every day of operation. Skill at making this decision is itself strategically critical enough to merit consideration as a CC [14,15].

"Make-versus-buy" is a traditional term for this challenge, and appears in the index of many business textbooks, especially in accounting, economics, and operations. To avoid the slight materials centrism in that term, this article will use "insource-versus-outsource" since many such evaluations concern the procurement of services rather than goods.

The academic and practitioner literatures overflow with commentaries on this topic. Most provide qualitative lists of issues to

consider or questions to ask, but leave to the decision maker any specific quantification of the multidimensional trade-offs (or authority to make a judgment call). This is not a criticism of the extant work, but an acknowledgment of the complexity and context-specificity of the problem. Here, we will simply sketch as an illustrative example one such insource-versus-outsource decision framework.

We earlier mentioned the high level strategic sound bite advocating for focusing on CCs and outsourcing everything else, a thread that can be traced through Refs 3 and 4. An oft-invoked variant of this is the notion of “core-versus-context” articulated by Geoffrey Moore of The Chasm Group [16], which has influenced strategy at firms like Cisco Systems. This defines “core” as those activities that differentiate a company in the marketplace and thereby drive the company stock’s valuation, whereas “context” is everything else the company does, and advises assigning the best people to the core while outsourcing as much of the context as possible.

An example of how these ideas might be operationalized is the seven-part framework of Quinn and Hilmer [4]:

1. Do we really want to produce the good or service internally in the long run? If we do, are we willing to make the back-up investments necessary to sustain a best-in-world position? Is it critical to defending our CC? If not,
2. Can we license technology or buy know-how that will let us be best on a continuing basis? If not,
3. Can we buy the item as an off-the-shelf product or service from a best-in-world supplier? Is this a viable long-term option as volume and complexity grow? If not,
4. Can we establish a joint development project with a knowledgeable supplier that ultimately will give us the capability to be best at this activity? If not,
5. Can we enter into a long-term development or purchase agreement that gives us a secure source of supply and a proprietary interest in knowledge or other property of vital interest to us and the supplier? If not,

6. Can we acquire and manage a best-in-world supplier to advantage? If not, can we set up a joint venture or partnership that avoids the shortcomings we see in each of the above? If so,
7. Can we establish controls and incentives that reduce total transaction costs below those of producing internally?

This set of questions implies a flowchart terminating in a spectrum of possible structures (“full ownership,” “partial ownership,” “joint development,” “retainer,” “long-term contract,” “call option,” and “short-term contract”) that exchange control (greatest with full ownership) for flexibility (greatest with short-term contract). A key message in this is that insource-versus-outsource is not a binary decision. For a single activity, a firm may even choose to outsource a portion while performing the rest in-house. This risk-mitigation strategy is sometimes termed *partial integration*, *taper(ed) integration*, or simply *make-and-buy* [17,18]. Furthermore, significant activities invariably contain many subtasks. A firm should consider various permutations of these that differ in divisions of labor, relationship lengths, and ownership of assets and liabilities.

Further complicating the matter is that the factors that drive the insource-versus-outsource decision are constantly in flux, so that the correct decision will be a moving target. Linder [1] and many others [19,20] emphasize the dependence on the stage in the life cycle of the company and industry. Even within a given industry, a particular set of environmental stimuli might elicit disparate responses from direct competitors. For instance, the recent global economic slowdown has directly led some consumer electronics firms to insource more production activities (to maintain utilization of existing in-house capacity) while others increased their outsourcing (to lower costs and achieve flexibility for responding to demand volatility).

Robust quantitative frameworks are elusive here for many of the reasons that apply to all complex managerial decisions with strategic impact. The individual consequences, such as a sharpening of

organizational focus or the atrophy of the knowledge and capabilities that are preserved only by regularly doing a task oneself, are very hard to translate into dollars and cents. Measuring the true cost of coordination across organization boundaries is also thorny. Certainly the contract delineates explicitly the transfer of funds, and salary impacts can be tallied. But how does one quantify an increase in the difficulty in communication? How does one measure the increased risk of opportunistic behavior by service providers, the possibilities of which are only limited by one's imagination? Existing accounting frameworks, which already struggle to assess the true cost of performing activities in-house, are stressed even further by outsourcing. McIvor [21] articulates an "overhead allocation fallacy" in standard cost accounting: when an activity is partially outsourced, certain overhead costs (which were not liquidated in the course of outsourcing) tend to be allocated to the activities that remain in-house, making those activities look even worse relative to outside alternatives. This can encourage further outsourcing and thereby perpetuate the fallacy.

ADVICE ON MANAGING THE OUTSOURCING RELATIONSHIP

The notion of best practices is largely idiosyncratic to the type of activity being considered for outsourcing, and attempting to unify all these context-specific details would go beyond the charter of this article. Here, we simply summarize the themes that overarch the extant body of academic and practitioner knowledge.

The obvious, yet profound, first concern is to carefully evaluate whether to outsource the particular activity at all. Outsourcing is a strategic action that must not be undertaken with the single-minded objective of reducing costs, or under the influence of herd mentality. The decision maker must be open to the possibility that outsourcing may actually increase overall costs, but might willingly proceed anyway if the structural change adds new capabilities or enhances existing ones. Contemplation of the full range

of pros and cons, such as those articulated in the section titled "Advantages and Disadvantages of Outsourcing", will affirm that outsourcing is no panacea. It is most prudently viewed as exchanging one set of headaches for another. Doig *et al.* [6] caution, "Don't assume that it is easier to manage suppliers than to improve your company's own performance."

After deciding to proceed, the outsourcing party must exercise caution and vigilance, which means due diligence on service providers up front, determining whether to single-source or multisource and the closeness of the resulting relationship(s), carefully writing specifications, contemplating and structurally addressing potential incentive conflicts, and installing appropriate monitoring mechanisms. In this spirit, Allen and Chandrashekar [22] and Aron and Singh [23] discourage outsourcing a process until it is well-understood and has coherent metrics. This can be harder to achieve for procured services than for procured materials, in part because the intangibility of what is being purchased complicates quality assessment and retrospective attribution of liability for problems [22]. Consequently, the outsourcing party must accept the need to invest resources (and maybe even add new headcount) in new control processes, which must be cost-justified based on the value delivered over the lifetime of the sourcing relationship. Priority shifts to skills such as relationship-building, negotiation, program and project management, and contract management. Peisch [24] points out that "Managing external resources requires an entirely different set of skills than managing the same services internally."

These challenges fall under the purview of the well-established discipline of purchasing and supply management. This community has established active professional organizations (e.g., the Institute for Supply Management (ISM), founded in 1915), certifications [e.g., the ISM's Certified Purchasing Manager (CPM) and Certified Professional in Supply Management (CPSM) credentials], university undergraduate and graduate degree programs, and a rich body of practitioner and academic literature (e.g.,

textbooks such as Monczka *et al.* [25] and numerous journals).

ORMS RESEARCH ON OUTSOURCING

The body of existing ORMS research on outsourcing is either too vast to survey in one article, or nascent, depending on one's definition of ORMS and the criteria used to determine what counts as work on outsourcing.

Mathematical modeling approaches popular among those who identify with the ORMS community are also used in other academic disciplines, including economics, accounting, and finance. All of these have studied issues relevant to the outsourcing decision. For reasons of tractability, the analytical work tends to focus on the trade-offs among a very small number of factors, primarily the ones easier to quantify. The limitations of this should be apparent from the preceding discussion. Questionnaire or interview-based descriptive surveying is a more popular format (many of this article's citations are of this sort), but this is not traditionally viewed as ORMS.

What counts as research on outsourcing? In the broadest sense, any model that includes a transaction between a supplier and a buyer firm could qualify. Such research has gone on for decades, and has generated thousands of publications. However, this author's position is that the outsourcing literature should be defined more narrowly as those works that consider the design, management, and control of an outsourcing relationship and give guidance about addressing some problem explicitly ascribable to the outsourcing.

A wish-list of specifications for an analytical, prescriptive research piece about outsourcing might include the following set of features, which does seem mathematically intractable:

- multiple parties: buyer, service provider, possibly a materials supplier, and competition for each;
- conflicting agendas, possibly also with internal conflict among agents within each firm;
- multi-attribute objective functions;

- private information that renders complete monitoring of the service provider impossible, so as to allow the possibility of deliberate deception;
- a cost model for buyer activities that reflects changes in organizational complexity, since outsourcing reduces complexity in some respects (in enabling focus on CCs) but increases it in others (for managing the service provider);
- institutional knowledge, since outsourcing jeopardizes the retention of this;
- power, since outsourcing creates dependence on outside parties.

Even this challenging list is not complete, since it does not address numerous other issues presented throughout this article, phenomena that are often difficult to quantify. Also, the best wisdom available is that firms must think of these factors strategically, and not be overly focused on short-term financial impact. This necessitates a longer-term (and more difficult to define) objective function.

This discussion should make clear why ORMS work that could truly be said to capture the essence of the outsourcing phenomenon is still sparse. Since this article was not meant to be a literature review, we will simply end here urging the reader to consider this as a roadmap to many important research opportunities.

ADDITIONAL READING

Due to publication restrictions, the bibliography for this article was limited to a small number of references. A fully annotated version containing more than 65 references is available for download at the author's university webpage.

BYELORUSSIAN OPERATIONAL RESEARCH SOCIETY (ByORS)

VALERY S. GORDON*
NIKOLAI N. GUSCHINSKY
United Institute of Informatics
Problems, National Academy of
Sciences of Belarus, Minsk,
Belarus

The Byelorussian Operational Research Society (ByORS) is a nonprofit scientific organization which supports application and promotes development of operations research (OR) methods in the Republic of Belarus. It unites experts in the fields of OR, applied mathematics, mathematical economy, and their applications. As a nationwide association, the ByORS also represents Belarus in the international network of experts in the field of operations research such as the Association of European Operational Research Societies (EURO) and the International Federation of Operational Research Societies (IFORS). The objectives of the BYORS are

- encouraging theoretical and applied research in the field of operational research in Belarus;
- promoting international connections and gaining the prestige of the Byelorussian scientists and experts who work in the field of OR.

To realize these objects, ByORS concentrates on the following:

- conducting scientific research and applied work in the field of OR;
- forecasting and promoting the new perspective branches of OR;

- conducting the independent scientific expertise of projects in the field of OR, formulating the reasonable recommendations for their practical application;
- dissemination of achievements in the field of OR by means of giving lectures, publishing books and articles, creating popular scientific programs, and using mass media;
- editorial activities in publishing the scientific, popular scientific literature, handbooks in the field of OR;
- organizing conferences, seminars, exhibitions, and meetings in the field of OR;
- encouraging the teaching of OR.

In order to achieve these objectives, the activities of the ByORS include editing and advertising; publishing the results of scientific research; organizing interconnections with scientific and industrial associations; promoting cooperation with firms, universities, and institutions; participating in international scientific congresses, conferences, symposia, meetings, exhibitions, and other events.

HISTORY AND MILESTONES

The ByORS was founded in November 1996 at the Institute of Engineering Cybernetics of the National Academy of Sciences of Belarus (NASB). Foundation of the ByORS was initiated by Vyacheslav S. Tanaev who was a full member of the NASB and the director of the United Institute of Informatics Problems (UIIP) of NASB. Tanaev became the first President of the ByORS and remained in this position until his death in the year 2002. What follows is a citation from the paper "Vyacheslav Tanaev: Contributions to Scheduling and Related Areas" by Valery S. Gordon, Mikhail Y. Kovalyov, Genrikh M. Levin, Yakov M. Shafransky, Yuri N. Sotskov, Vitaly A. Strusevich, and Alexander V. Tuzikov submitted to a special issue

*Deceased June 4, 2010.

of “Journal of Scheduling” (2010) which is dedicated to the memory of V.S. Tanaev on the occasion of his 70th birthday. Vyacheslav Tanaev (1940–2002) was born in village Akulovo, Tver region, Russian Federation. He received his Candidate of Sciences (PhD equivalent) degree for his work on scheduling from the Institute of Mathematics of the NASB in 1965. The degree of Doctor of Sciences (Habilitation Doctor) was awarded to V.S. Tanaev after a successful defense of the thesis on parametric decomposition of optimization problems at the Computer Center of the Academy of Sciences of the USSR, Moscow, in 1977. In 1987 he became the director of the UIIP of NASB, and in 2000 was elected a full member of NASB, which is the highest scientific rank in the states of the former Soviet Union. Scientific heritage of Vyacheslav Tanaev includes more than 130 research publications among which there are 10 monographs. His scientific interests included scheduling theory, discrete and continuous optimization, computer-aided design (CAD); he coordinated research in geo-information systems, development of supercomputers, and applications of informatics to medicine. He supervised 18 candidates of sciences among which 6 became Doctors of sciences. Vyacheslav Tanaev is the author of the first papers on scheduling in Russian, and his early research stimulated the study in this area in the Soviet Union and the countries of Eastern Europe. Several generations of Russian-speaking researchers benefited from becoming familiar with the major results on scheduling by studying his monographs.

From October 2002, Valery S. Gordon (Prof., Dr., Principal researcher of UIIP) served as president of ByORS. There are three vice presidents of ByORS: Prof. Dr. Vladimir A. Golovko from Brest State Technical University, Prof. Dr. Mikhail Y. Kovalyov (Deputy General Director of UIIP), and Dr. Genrikh M. Levin (Head of OR laboratory of UIIP). Dr. Nikolai N. Guschinsky is the secretary of ByORS.

MAIN ACTIVITY

The ByORS focuses on the following OR topics:

- theory and practice of optimization;
- scheduling theory;
- supply chain management;
- multicriteria optimization;
- graph optimization problems;
- decision support system problems;
- methods and software for production planning;
- methods for project management and scheduling;
- decomposition methods of optimization problems;
- synthesis of logical circuits;
- OR in manufacturing;
- OR in CAD\CAE\CAM;
- OR in finance;
- OR in health care.

Members of ByORS give courses and lectures on topics in OR at the Belarus State University (BSU) and the Belarus National Technical University as well as supervise postgraduate students in the field of OR at the BSU and the NASB. Members of ByORS conduct their scientific projects and publish papers in the field of OR, and they take part in scientific councils and juries on thesis defenses.

The ByORS organized the international workshop “Discrete optimization methods in scheduling and computer-aided design” (Minsk, Belarus, 2000), the first international workshop on “Discrete optimization methods in production and logistics” (Minsk, 2002), and took part in the organization of the Conference of the European Chapter on Combinatorial Optimization (ECCO) “Combinatorics for modern manufacturing, logistics, and supply chains” (ECCO XVIII, Minsk, 2005). Members of the ByORS also took part in organizing the second international workshop “Discrete optimization methods in production and logistics” (Omsk—Irkutsk, Russia, 2004), the international scientific

conference “Discrete mathematics, algebra and applications” (Minsk, 2009).

Beginning from 2003, ByORS has organized the biannual international conference “The Tanaev readings” in Minsk. The conference is dedicated to the memory of Vyacheslav Tanaev (the first president of ByORS) and brings together researchers, academicians, practitioners, and students interested in all branches of operational research. The topic of the first of these conferences was “Scheduling theory and decomposition methods,” and the scope of the conference was later broadened to include other branches of OR and information technology. The 4th international conference “The Tanaev readings” took place in Minsk in March 2010.

President of ByORS V.S. Gordon, Vice President M.Y. Kovalyov, and member Prof. V.A. Strusevich are the editors of a special issue “Scheduling: new branches, old roots” of the *Journal of Scheduling* which is dedicated to the memory of Vyacheslav Tanaev on the occasion of his 70th birthday.

Members of the ByORS took part in most global (IFORS) and European conferences in the field of OR, being Chairpersons of sessions and streams or members of program committees (in particular, president of ByORS Prof. V.S. Gordon was a member of the program committee of the 20th ECOR, Rhodes, Greece, July 4–7, 2004; Vice President Dr. G.M. Levin was a member of the Program Committee of the 13th IFAC symposium on information control problems in manufacturing INCOM 2009, Moscow, June 3–5, 2009; Vice President

Prof. M.Y. Kovalyov was a chairperson and V.S. Gordon was a cochairperson of the program and organizing committees of the international conference ECCO XVIII, Minsk, May 26–28, 2005; member of the ByORS Prof. A.B. Dolgui was a member of the advisory, scientific or program committees of several international conferences. He was also an international program committee chair of the symposiums INCOM 2006 (Saint Etienne, France, May 17–19, 2006) and INCOM 2009.

Members of ByORS serve in the editorial boards of the international journals: M.Y. Kovalyov and A.B. Dolgui are associate editors for “OMEGA—The International Journal of Management Science” and “Asia-Pacific Journal of Operational Research”; M.Y. Kovalyov is a member of the editorial advisory board for “European journal of operational research”; V.A. Strusevich and M.Y. Kovalyov are members of editorial advisory board for “Computers and operations research”, A.B. Dolgui is an area editor for the journal “Computers and industrial engineering”, member of the editorial board for the “International journal of production economics,” “International journal of systems sciences,” “Journal of mathematical modeling and algorithms,” and “Journal of decision systems.”

Members of the ByORS work at the universities, institutes, scientific and project organizations and firms in Minsk, Grodno, Brest, Gomel, and Mogilev (Belarus) as well as in London, Leeds (Great Britain), Saint Etienne (France), and Olsztyn (Poland).

CALCULATING REAL OPTION VALUES

MARCO ANTONIO GUIMARÃES DIAS
Department of Industrial Engineering,
PUC-Rio, Rio de Janeiro, Brazil
Financial Planning, Petrobras, Brazil

INTRODUCTION

A real option (RO) is the right, but not the obligation, an agent has for making decisions over a real asset. The agent can be a manager, a consumer, a social planner or any other decision maker. The real asset can be an investment project opportunity or an already existing asset like a factory. RO highlights the *flexibility* value, which is more valuable under conditions of uncertainty. RO can be viewed as a problem of *optimization under uncertainty*: maximize the real asset value by exercising optimally the relevant options subject to the uncertainties and physical and other constraints. Typically, RO considers the optimal *timing* to exercise the option(s). RO uses *dynamic programming* and *optimal control* concepts from *operations research* school, but RO incorporates concepts from modern finance, for example, asset pricing models must be free of *arbitrage* opportunity, which has an impact on discount rates and probabilities used in the quantitative model.

Myers [1] coined the term *real options* in the 1970s for the growth opportunities faced by firms, adapting the concept of financial options pioneered by Black and Scholes [2], and Merton [3]. The value of an RO is linked with the optimal decision (exercise rule). While *financial* options/derivatives theory is the *valuation* root of RO, the *decision* roots of RO are *decision analysis* [4] and *environmental economics* [5].

The first mathematical model appeared in 1979 [6], but textbooks on RO appeared only in the 1990s [7,8]. More than 50 books have

been published now (textbooks and edited books) on RO; books on corporate finance and valuation [9,10], as well as several books on derivatives [11,12], usually have one or more chapters on real options.

The traditional economic valuation approach for projects is the *discounted cash flow* (DCF) that uses a *risk-adjusted discount rate* (μ) to calculate the present value of *expected* cash flows, thus obtaining the (expected) *net present value* (NPV). If the NPV is positive, the project can be accepted. Let V be the value of the operating project and I the investment value so that

$$\text{NPV} = V - I. \quad (1)$$

In cash flow terms, V can be interpreted as the present value of expected operational cash flows (revenues net of operational costs and taxes), whereas I is the present value of the expected investment (net of tax benefits like depreciation).

Consider two *mutually exclusive alternatives* to invest in a project, investment at $t = 0$ with $\text{NPV}_0 = V(t = 0) - I$, and investment at one period later ($t = 1$) with $\text{NPV}_1 = e^{-\mu} E[V(t = 1) - I]$, where the first term is the discount factor in continuous time, V is stochastic, and I is deterministic. By the traditional DCF approach the value of this investment opportunity is

$$\begin{aligned} W &= \text{Max}[\text{NPV}_0, \text{NPV}_1, 0] \\ &= \text{Max}[V(t = 0) - I, e^{-\mu} E[V(t = 1) - I], 0]. \end{aligned} \quad (2)$$

Consider the following numbers: $V(t = 0) = 100$, $I = 100$, and two equiprobable scenarios for $V(t = 1)$: $V^+ = 120$ and $V^- = 80$. With these numbers in Equation (2), the DCF value is $W = 0$, because $\text{NPV}_0 = \text{NPV}_1 = 0$.

The same example under the RO approach shows a very different result. Consider $\mu = 10\%$. If we wait until $t = 1$ and consider the options (invest or not) in *each scenario* at $t = 1$ (instead $E[V(t = 1)]$), the RO value at

$t = 1$ is $F(t = 1) = E[\text{Max}\{V - I, 0\}] = 50\% \times \text{Max}\{V^+ - I, 0\} + 50\% \times \text{Max}\{V^- - I, 0\} = 0.5 \times 20 + 0.5 \times 0 = 10 > 0$. The RO value of this investment opportunity at $t = 0$ could be calculated as

$$\begin{aligned} F &= \text{Max}\{\text{NPV}_0, e^{-\mu} F(t = 1)\} \\ &= \text{Max}\{V(t = 0) - I, \\ &\quad e^{-\mu} E[\text{Max}\{V(t = 1) - I, 0\}]\}. \end{aligned} \quad (3)$$

Substituting the numbers, $F = 9.05 > W = 0$. The mathematical difference between Equations (2) and (3) is that the latter uses $E[\text{Max}\{.\}]$ whereas the former uses $\text{Max}\{E[.]\}$. This result is very general: by the *Jensen's inequality* if $f(x)$ is a strictly *convex function* and x is a random variable (rv), then

$$E[f(x)] > f(E[x]). \quad (4)$$

Note that $\text{Max}\{V(t = 1) - I, 0\}$ is a convex function in V , as in almost all RO cases. The difference between the two sides of this inequality generally increases with the variance of x . This explains the stylized fact that the option value increases with volatility. This intuitive discussion shows that optionality generates value and it does not depend on *how* an RO is calculated. This example is similar to examples from Dixit and Pindyck

[7, Chapter 2], but it is used only for incomplete markets. The section titled “The Two Main Derivatives Valuation Ideas” addresses the method of calculation using finance theory, for example, discussing the option discount rates problem. Incomplete market is discussed in the section titled “Other Real Options Issues and Concluding Remarks”.

The previous example is the *investment timing* option, but there are many types of ROs and many ways to classify the types of ROs. Trigeorgis [8, p. 145] divides the cases of *proprietary* (only one agent owns) versus *shared* RO, as well as the cases *simple* versus *compound* (option on another option) and *expiring* versus *deferrable* RO. We could also consider cases of *European* RO (only exercisable at the expiration) versus *American* RO (exercisable at any date including the expiration), *perpetual* (never expires) versus *finite-lived* RO. But the article follows a more practical RO classification to ease the identification of the project's relevant ROs and the selection of the valuation method. Figure 1 proposes this classification.

Figure 1 shows the three main types of ROs. The first group is related to the investment itself; the second is *after* the investment, and the third is the learning RO. Timing RO (or *option to wait* or *option to delay*) can be simple, as in the previous example (the general case is the classical

Figure 1. Classification of real options.

RO; see McDonald and Siegel [13] and the section titled “Continuous-Time Approach: Risk-Free Portfolio”), considering the time to build the project (used for applications with a long investment period before the revenues as in nuclear plants, see Majd and Pindyck [14] and Pindyck [15]) and compound options (e.g., timing to invest in a project with operational RO like abandonment). Operational RO includes expansion (with additional investment) and contraction (decreasing the operational cost), temporary and permanent (abandonment) stopping, and many switch ROs (input, output, use, and location). Learning RO generally is performed before considering industrial-scale investments and typically uses Bayesian methods. Some authors use the term *growth options* for operational-expansion options or for learning options (investment in R&D can be labeled as growth option or as learning option). Exogenous learning with market uncertainty is just another label for the option to wait. The case of strategic uncertainty about the type of an agent, for example, uncertainty about the behavior of a competitor in a market, can be modeled with Bayesian game theory combined with RO theory: a real option game model [16]. All shared ROs, for example, any two firms considering an entry into a new market (shared-timing options), can use option game models [17].

In many cases it is possible to design a business (with additional investment) to ease the exercise of operational options, for example, by acquiring a neighboring vacant land when investing in a new factory in order to make the exercise of the RO to expand production in case of high demand cheaper. RO quantification can be necessary to decide whether or not to make the additional investment to provide flexibility in a plant, for example, dual-fuel electricity generation (*switch-input* option) versus single-fuel generation. Although limited, petroleum refinery and GTL (gas-to-liquid) plants are examples of *switch-output* RO. One example of *switch-use* RO is an urban land with a house; the land can be redeveloped to build a hotel. Examples of *switch-place* RO are the mobile thermogenerators (typically ~ 100 MW) in containers, trucks or boats that are

used in remote regions or in regions with temporary shortage of electricity supply.

One interesting real-life switch RO case occurred in the Brazilian automobile industry. Owing to the petroleum price shocks in the 1970s, Brazil initiated the *ethanol-fuel automobile* production in the 1980s. But with the low petroleum prices in 1990s (dropping the fuel-ethanol prices), the owners of sugar mills preferred to make sugar instead of ethanol (*switch-output* RO), leaving the service station without ethanol for the customers. The ethanol car fabrication practically disappeared with the fall of the consumer confidence in ethanol automobiles. But in the 2000s, a new technology appeared in Brazil: the *flex-fuel car* using gasoline or ethanol (in some cases the natural gas as third fuel option). The flex-fuel car provides *switch-input* RO for the *consumer* so that they do not have to fear anymore about the producer switch-output (sugar–ethanol) option. By 2010, almost all automobiles sold in Brazilian market (>3 million per year) were flex-fuel. The best antidote to the producers’ switch option was the consumers’ switch option! The flex-fuel technology increased the consumer confidence and boosted the automobile market demand, leaving everybody better: ethanol producers, automobile producers, and the consumers. An RO that had a happy ending!

THE TWO MAIN DERIVATIVES VALUATION IDEAS

A very important concept for calculating the fair value of an asset is *arbitrage*, which is the possibility to get a riskless profit without investing money. Markets in equilibrium must be free of arbitrage opportunities as well as have good asset pricing models. Before the seminal derivatives articles [2,3] appeared, the key question was the option/derivatives risk-adjusted discount rate. While the risk of a derivative $F(V)$ is linked with the risk of the underlying asset V , clearly the risks are different (derivative can amplify or reduce the underlying risk) and so is the option’s risk-adjusted discount rate. The derivatives discount rate is a

complex problem, but the following idea bypasses this problem. If we can build a riskless portfolio with a certain combination of derivatives and basic assets, then the expected return (and so the discount rate) must be the risk-free discount rate; otherwise we can get an arbitrage opportunity [11,12].

The article now discusses the concepts of *riskless portfolio* and the *change of probability measure*, which constitute the two main derivatives calculation concepts underlying many RO valuation approaches.

Consider the following simple discrete-time options framework (Fig. 2), where the basic asset V is known at $t = 0$, but uncertain at $t = 1$. The aim is to calculate the fair value of the derivative $F(V)$ at $t = 0$. Figure 2a shows that the asset V (for example, the value of an operating factory) at $t = 1$ can rise to V^+ with probability p or can decrease to V^- with probability $(1 - p)$. In addition, V generates cash flow (analogous to “dividends” of financial assets) with values c^+ and c^- in each state at $t = 1$. The derivative $F(V)$ is a function of V . Hence, given the future values V^+ and V^- , F^+ and F^- are known. The unknown is the *present value* of F because we do not know its discount rate. With V, V^+, V^-, c^+, c^- we can calculate the total return μ of the underlying asset V , which (capital asset pricing model, CAPM) in equilibrium is also the risk-adjusted discount rate for V , but this discount rate of $F(V)$ is not the same and it is a complex problem. The initial idea to solve

this problem is by building a riskless portfolio Φ so that (by nonarbitrage argument) the return must be the risk-free discount rate r . Figure 2b proposes this portfolio:

$$\Phi = F - nV, \quad (5)$$

where n is chosen so that the portfolio is riskless, that is, the value at $t = 1$ is the same: $\Phi^+ = \Phi^-$. The value of n is known as *delta-hedge* and is written as

$$n = \frac{\Delta F}{\Delta V} = \frac{F^+ - F^-}{(V^+ + c^+) - (V^- + c^-)}. \quad (6)$$

By substituting n in Φ^+ and Φ^- (see Fig. 2b), they are equal (riskless portfolio) as desired.

$$\Phi^+ = \Phi^- = \frac{F^-(V^+ + c^+) - F^+(V^- + c^-)}{(V^+ + c^+) - (V^- + c^-)}. \quad (7)$$

Letting $u = \text{upside} = (V^+ + c^+)/V$ and $d = \text{downside} = (V^- + c^-)/V$, we can rewrite Equation (7) as

$$\Phi^+ = \Phi^- = \frac{uF^- - dF^+}{u - d}. \quad (8)$$

So, the present value of this *riskless* portfolio is easily calculated with the risk-free discount rate r :

$$\Phi(t=0) = \frac{uF^- - dF^+}{(u - d)(1 + r)}. \quad (9)$$

Figure 2. Discrete-time options and the risk-free portfolio.

Because we know all the inputs of Equation (9), we know $\Phi(t=0)$. Hence, we can calculate the derivative $F(t=0)$ by using Equation (5):

$$F(t=0) = \frac{uF^- - dF^+}{(u-d)(1+r)} + nV.$$

Using Equation (6) and the definition of u and d , the derivative value can be calculated with

$$F(t=0) = \frac{uF^- - dF^+}{(u-d)(1+r)} + \frac{F^+ - F^-}{u-d}. \quad (10)$$

It is the first way to calculate the derivative value without requiring the derivative discount rate. It uses the concept of nonarbitrage. The riskless portfolio is like a riskless bond, $\Phi(t=0) = B$, and this suggests that we can replicate a derivative with a bond B and n underlying assets V by rewriting Equation (5) as

$$F = B + nV. \quad (11)$$

The analysis above can be generalized for several underlying assets. For example, in the case of two assets V and W , the risk-free portfolio will be $\Phi = F(V, W) - nV - mW$, where $n = \Delta F / \Delta V$ and $m = \Delta F / \Delta W$.

The second calculation concept is the change of probability: the total return on V under *real* probability measure P (here p and $1-p$) is μ , but we can change the probability measure in a way that instead of μ , the *total* return (including the cash flows or dividends) is the risk-free return r . This probability measure Q (here q and $1-q$) is named *risk-neutral probability* or *equivalent martingale measure*. The risk-free return under Q is

$$\begin{aligned} r &= \frac{E^Q[V(t=1) + c(t=1)]}{V(t=0)} - 1 \\ &= \frac{q(V^+ + c^+) + (1-q)(V^- + c^-)}{V} - 1. \end{aligned}$$

Using the definitions of u and d , we get the risk-neutral probability q for the asset V :

$$q = \frac{1+r-d}{u-d}. \quad (12)$$

The key issue is that the risk-neutral probability for V also makes the return of the derivative or function $F(V)$ be the risk-free return r . In order to see this, let q' and $(1-q')$ be the probabilities that make the derivatives' rate of return equal to r , that is,

$$r = \frac{q'F^+ + (1-q')F^-}{F(t=0)} - 1. \quad (13)$$

Using the replication portfolio, that is, Equation (11) for F and equations from Fig. 2b for F^+ and F^- in Equation (13), we get the risk-neutral probability q' for the derivative $F(V)$:

$$q' = \frac{1+r-d}{u-d}, \quad (14)$$

which is exactly the same risk-neutral probability of V , that is, $q' = q$. Hence, the probability measure that makes the underlying asset V return the risk-free rate r is the same probability that makes the function $F(V)$ return the risk-free rate r . Hence, under risk-neutral probabilities q and $1-q$, the correct discount rate for $F(V)$ is also r . Hence, there is another way to calculate the present value of the derivative $F(V)$:

$$F(t=0) = \frac{qF^+ + (1-q)F^-}{(1+r)}. \quad (15)$$

Note that the risk-neutral probability q depends only on the dynamics of the underlying asset V (information about the dynamics of F is redundant and not required). In many cases, this method is easier to apply than the riskless portfolio presented before. On the basis of this risk-neutral approach, the method named *binomial* was developed [18], with a recombining tree in order to solve multiperiod derivatives valuation (Fig. 3). The tree is solved *backward*, as in *dynamic programming*, where each node compares the present value of waiting (using Eq. 15) with the immediate exercise payoff (e.g., Eq. 1), rolling back until the initial date. For a bivariate binomial application with another model for the uncertainties (mean-reversion), see Bastian-Pinto *et al.* [19]. Other *lattices* with similar approaches are also used in ROs, for example, *pentanomial* [20]. The binomial/lattice approach

Figure 3. Recombining tree: the binomial diffusion.

is popular because it is more intuitive than continuous-time approach, but it is not good for perpetual ROs (differential equation or integral methods that get closed-form solutions in most cases are preferable, see the sections titled “Continuous-Time Approach: Risk-Free Portfolio” and “Continuous-Time Approach: Change Of Probability Approaches”), and to model three or more sources of uncertainties (Monte Carlo simulation is preferable, see the section titled “Continuous-Time Approach: Change Of Probability Approaches”).

These ideas allow us to calculate present values of derivatives, including RO. For example, a manager has the option to invest I in $t = 0$ or in $t = 1$ or not to invest. The NPV of immediate investment is $V(t = 0) - I$. Consider the investment deterministic, but the underlying asset value V is stochastic (as in Fig. 2). The values of F^+ and F^- are

$$F^+ = \text{Max}[V^+ - I, 0], \quad (16)$$

$$F^- = \text{Max}[V^- - I, 0]. \quad (17)$$

The present value of waiting can be calculated with either Equation (10) or Equation (15). The RO value is simply the maximum value between the immediate exercise and the present value of waiting:

$$\text{RO value} = \text{Max}[V - I, F(t = 0)]. \quad (18)$$

Note that $F(t = 0)$ will always be nonnegative, so that in many cases a (small) strictly

positive NPV is not enough to decide on investing immediately because the waiting value is higher. It is not difficult to see, because of the discount factor < 1 , that there exists a sufficiently high current value of V , say V^* , for which we are *indifferent* between waiting and immediate option exercise, that is, $F(t = 0) = V^* - I$. This suggests an optimal investment rule: invest immediately if $V(t = 0) \geq V^*$. This critical value V^* is known as *threshold* and is a very important RO concept. For the more general case of multiple periods we can calculate a threshold *curve* $V^*(t)$. The section titled “Continuous-Time Approach: Risk-Free Portfolio” presents a continuous-time framework with a threshold curve for finite-lived RO.

Most RO valuation methods are based on the two ideas presented above that can be generalized for the continuous-time framework.

Figure 4 presents the main RO solution methods. The risk-free portfolio in discrete time was presented above. The next section presents the continuous-time case, which results in a differential equation that describes the arbitrage-free relation between the derivative and its underlying asset. From the change of probability concept we have, in addition to the binomial approach presented above, many other approaches. One powerful method using this concept is the risk-neutral Monte Carlo simulation of the underlying assets’ stochastic processes together with an optimal decision rule, which is useful for the case of many stochastic variables (see the section titled “Continuous-Time Approach: Change Of Probability Approaches”). Dynamic programming under uncertainty but using the risk-neutral expectation operator and discounting with risk-free rate is another approach, which in continuous-time results in the same differential equation (see the section titled “Continuous-Time Approach: Risk-Free Portfolio”). The integral method is based on the first moment that a risk-neutral stochastic process hits a threshold for optimal investment and is particularly useful for perpetual options (at the end of the section titled “Continuous-Time Approach: Risk-Free Portfolio”).

Figure 4. Real option solution methods.

CONTINUOUS-TIME APPROACH: RISK-FREE PORTFOLIO

Now, consider a more general mapping of uncertainties described by a *continuous-time stochastic process*. Let V be the value of a project that follows an *Itô process* described by the differential equation

$$dV = a(V, t) dt + b(V, t) dz, \quad (19)$$

where $a(V, t)$ is the drift of this process (function of V and time), $b(V, t) dz$ is the random term, and dz is the *Wiener increment* denoted by

$$dz = N(0, 1)\sqrt{dt}, \quad (20)$$

where $N(0, 1)$ is the standard normal distribution. The most popular stochastic process used in ROs and in finance is the geometric Brownian motion (GBM), denoted by

$$dV = \alpha V dt + \sigma V dz. \quad (21)$$

Hence, it is an Itô process with $a(V, t) = \alpha V$ and $b(V, t) = \sigma V$, where α is the exponential growth rate of V (the capital gain) and σ is the volatility, which is the standard deviation of dV/V . In Equation (19), V is the (known) current asset value, but dV is stochastic.

Another important particular case used in many cases to model commodity prices is the *mean reverting process* that has some variations, and one of them is

$$dV = \eta (\bar{V} - V) dt + \sigma V dz, \quad (22)$$

where η is the reversion speed and $\bar{V}$ is the long-run equilibrium level of V . In some applications, the Itô process is combined with a Poisson (jump) process, as discussed in Dias and Rocha [21].

The main *stochastic calculus* tool used in RO is the *Itô Lemma* [7, Chapter 3]. For the case of two state variables, V and t , where V follows Equation (21), the Itô Lemma for $F(V, t)$ is as follows:

$$dF = \frac{\partial F}{\partial V} dV + \frac{1}{2} \frac{\partial^2 F}{\partial V^2} (dV)^2 + \frac{\partial F}{\partial t} dt. \quad (23)$$

Because $(dz)^2 = dt$ [7, Chapter 3], $(dV)^2$ is not negligible if V is stochastic. For $n > 1$ rv, see Dixit and Pindyck [7, Chapter 3]. The second term in the right side quantifies the Jensen's inequality effect (if F is convex, this term is positive). If V follows Equation (19)

$$(dV)^2 = [b(V, t)]^2 dt. \quad (24)$$

Substituting Equations (19) and (24) into Equation (23)

$$dF = \left[a(V, t) \frac{\partial F}{\partial V} + \frac{1}{2} b^2(V, t) \frac{\partial^2 F}{\partial V^2} + \frac{\partial F}{\partial t} \right] dt + b(V, t) \frac{\partial F}{\partial V} dz. \quad (25)$$

Note that the partial derivatives are deterministic (V is known at t), and only dF and dz are stochastic. Equation (25) shows that $F(V, t)$ follows another Itô process:

$$dF = g(V, t) dt + h(V, t) dz. \quad (26)$$

Now, it is easy to prove that the value of n that makes the portfolio $\Phi = F - nV$ riskless is the partial derivative $\partial F / \partial V$. Consider the more general case where both the derivative $F(V, t)$ and the underlying asset V generate cash flows (dividends). In an infinitesimal time interval dt , the variations (capital gain plus dividends) for the portfolio components F and V are $dF + \delta_F F dt$ and $dV + \delta_V V dt$, respectively (δ_X is named *dividend yield* of X) so that the portfolio variation in dt is

$$d\Phi = dF + \delta_F F dt - n(dV + \delta_V V dt). \quad (27)$$

Substituting Equations (19) and (26) into Equation (27)

$$d\Phi = [k(V, t) - nc(V, t)] dt + [h(V, t) - nb(V, t)] dz, \quad (28)$$

where $k(V, t) = g(V, t) + \delta_F F$ and $c(V, t) = a(V, t) + \delta_V V$. Riskless portfolio means nonrandom $d\Phi$. Hence, the second term of Equation (28) must be zero. The value of n that makes the random term zero is $n = h(V, t) / b(V, t)$. But $h(V, t) = b(V, t) \partial F / \partial V$ (compare Eqs 25 and 26). So, the n that makes the portfolio Φ riskless is

$$n = \frac{\partial F}{\partial V}. \quad (29)$$

This result is analogous to the discrete-time result (in Eq. 6 we allow stochastic dividends for V).

If the portfolio is riskless with this choice of n , the portfolio return must be the risk-free

interest rate r because of nonarbitrage requirement. Hence, we can generate the nonarbitrage relation between F and V illustrated with the following example that results in the classical Black–Scholes–Merton *partial differential equation* (PDE).

Let V be the underlying asset that follows a GBM (Eq. 21) with dividend yield $\delta > 0$. Let $F(V, t)$ be a derivative that does not generate cash flow. With the convenient choice of n , the portfolio return is risk-free and equal to $r \Phi dt$ in the interval dt . But the portfolio return is also the variations of its components, so that we can write

$$r(F - nV) dt = dF - n(dV + \delta V dt). \quad (30)$$

The value of dF is given by the Itô Lemma (Eq. 23), where $(dV)^2 = \sigma^2 V^2 dt$ for GBM. Hence,

$$dF = \frac{\partial F}{\partial V} dV + \frac{1}{2} \sigma^2 V^2 \frac{\partial^2 F}{\partial V^2} dt + \frac{\partial F}{\partial t} dt. \quad (31)$$

Substituting Equations (31) and (29) into Equation (30) and rearranging, we get the classical PDE:

$$\frac{1}{2} \sigma^2 V^2 \frac{\partial^2 F}{\partial V^2} + (r - \delta) V \frac{\partial F}{\partial V} - rF + \frac{\partial F}{\partial t} = 0. \quad (32)$$

This PDE just gives the *nonarbitrage relation between F and V* . We do not yet say if F is an option, if it is a call or a put, if it is an American or European option, and so on. The *boundary conditions* make the case more specific.

Now, consider that V is the value of an operating project that can be obtained if the manager invests an amount I (deterministic). This RO is like a *financial call option*. Let T be the expiration of this RO (e.g., in petroleum sector, there is generally a last legal date that the oil company can develop a discovered oilfield), but the RO can be exercised at any date until T (American RO). This specific case

demands four boundary conditions (bc):

$$\text{If } V = 0, F(0, t) = 0, \quad (33)$$

$$\text{If } t = T, F(V, T) = \text{Max}[V - I, 0], \quad (34)$$

$$\text{If } V = V^*, F(V^*, t) = V^* - I, \quad (35)$$

$$\text{If } V = V^*, \left. \frac{\partial F(V, t)}{\partial V} \right|_{V=V^*} = \left. \frac{\partial(V - I)}{\partial V} \right|_{V=V^*} = 1. \quad (36)$$

Equation (33) is the *trivial* bc: if $V = 0$, Equation (21) shows that $dV = 0$, that is, V remains at zero forever (*absorbing barrier*) so that the right to invest $I > 0$ is worthless. Equation (34) shows that at expiration it is optimal to invest only with positive NPV (see Eqs 16 and 17 for the discrete-time case). Equation (34) is known as *value-matching* bc and shows that at any time it is optimal to invest at the threshold level V^* , which is defined as the indifference point where the waiting value F is equal (matches) to the exercise payoff $V - I$ (see discussion after Eq. 18). Equation (36) is known as *smooth-pasting* (or *high-contact*) condition and shows that not only the waiting value (F) and the exercise payoff (here $V - I$) values but also the slopes of the two functions match at V^* . The smooth-pasting is a *sufficient* condition (but not *necessary*) for the optimal option exercise (see Brekke and Oksendal [22] for a general proof).

The PDE (Eq. 32) and its bc (Eqs 33–36) are solved with numerical methods like *finite-differences* or with *analytical approximations*

[23] to calculate both the RO value $F(V, t)$ and the optimal exercise rule $V^*(t)$.

Figure 5 shows the $F(V, t)$ curve for some numerical parameters ($I = \$100$ million; $r = \delta = 4\%$ pa; $\sigma = 25\%$ pa) 2 years ($\tau = T - t = 2$) before expiration (dotted line) and at expiration ($t = T$, continuous line). Note the smooth-pasting contact of the dotted line with the exercise payoff line at V^* .

Figure 6 shows the threshold curve $V^*(t)$ for the same case. Note that at expiration $V^*(T) = I$, whereas 2 years before the expiration we have $V^*(t = 0) = \$155$ million $> I$ (shown also in Fig. 5).

This RO is a finite-lived American call option and was used in Paddock *et al.* [24] for oilfield development decision, where there is a legal period to develop the oilfield. But, in many cases the RO is *perpetual*, for example, the option to develop an urban land, where $F(V)$ is the land value and V is the house value. In this perpetual case, the partial derivative $\partial F / \partial t = 0$ so that the PDE (Eq. 32) simplifies to an *ordinary differential equation* (ODE):

$$\frac{1}{2} \sigma^2 V^2 \frac{\partial^2 F}{\partial V^2} + (r - \delta) V \frac{\partial F}{\partial V} - rF = 0. \quad (37)$$

In this perpetual option case, the threshold V^* is not a function of time anymore. Because there is no expiration, it remains valid only in Equations (33), (35), and (36) as boundary conditions. This ODE is *homogeneous* (all terms with F or their partial derivatives) and

Figure 5. Real option values $F(V)$.

Figure 6. Optimal exercise threshold curve $V^*(t)$.

has *analytical solution* of the type

$$F(V) = AV^\beta, \quad (38)$$

where A is a constant to be determined. Substituting Equation (38) and its derivatives into Equation (37), we get a quadratic equation for β , which has two roots:

$$\beta_1 = \frac{1}{2} - \frac{r - \delta}{\sigma^2} + \sqrt{\left(\frac{r - \delta}{\sigma^2} - \frac{1}{2}\right)^2 + \frac{2r}{\sigma^2}}, \quad (39)$$

$$\beta_2 = \frac{1}{2} - \frac{r - \delta}{\sigma^2} - \sqrt{\left(\frac{r - \delta}{\sigma^2} - \frac{1}{2}\right)^2 + \frac{2r}{\sigma^2}}, \quad (40)$$

where $\beta_1 > 1$ and $\beta_2 < 0$ [7, pp. 142–144]. With two roots, the solution is the linear combination

$$F(V) = A_1 V^{\beta_1} + A_2 V^{\beta_2}. \quad (41)$$

But due to Equation (33) the constant $A_2 = 0$ because with $\beta_2 < 0$ when $V \rightarrow 0$ the term in A_2 goes to infinity if $A_2 \neq 0$. Hence,

$$F(V) = A_1 V^{\beta_1} \quad (42)$$

The two unknowns that remain are the constant A_1 and the threshold V^* . We get these values by applying the solution of Equation (42) into Equation (35) and (36). This set of

two equations with two unknowns results in

$$V^* = \frac{\beta_1}{\beta_1 - 1} I, \quad (43)$$

$$A_1 = \frac{V^* - I}{(V^*)^{\beta_1}}. \quad (44)$$

Equations (42)–(44), and (39) solve this perpetual RO problem completely.

CONTINUOUS-TIME APPROACH: CHANGE OF PROBABILITY APPROACHES

This section discusses the application of change of probability measure for the continuous-time case. It uses *risk-neutral stochastic processes* for the underlying assets. The risk-adjusted discount rate μ is the risk-free interest rate plus a risk premium π (given generally by the CAPM):

$$\mu = r + \pi. \quad (45)$$

Finance theory says that in equilibrium μ is also the total expected rate of return, which is the sum of the expected capital gain rate (α) and the expected dividend yield (or cash flow yield) δ

$$\mu = \alpha + \delta. \quad (46)$$

Equating Equations (45) and (46) we get

$$\alpha - \pi = r - \delta. \quad (47)$$

While in GBM (Eq. 21) α is the drift, the left side of Equation (47) presents a drift

penalized by a risk premium. This penalized drift (as well as the right side $r - \delta$) is known as *risk-neutral drift* or *drift under martingale measure* Q . In order to give more intuition, we could substitute α in Equation (21) by Equation (46):

$$dV = (\mu - \delta)V dt + \sigma V dz. \quad (48)$$

Equation (48) is under *real* probability measure P . It may be recalled that the measure Q is so that the total return of V changes to the risk-free return r (replacing the total return μ). Hence, the GBM under risk-neutral measure Q is simply

$$dV = (r - \delta)V dt + \sigma V dz \quad (49)$$

or

$$dV = (\alpha - \pi)V dt + \sigma V dz. \quad (50)$$

Hence, the risk-neutral GBM is the same but with the drift penalized with a risk premium. Risk premium is subtracted from the drift also when building any other risk-neutral Itô process (Eq. 19). A more rigorous proof uses the Girsanov's theorem [25].

The *dynamic programming* (DP) approach breaks the sequence of decisions into two components, the *immediate decision* (e.g., invest or wait) and a *value function* that considers the consequences of all posterior decisions. Typical RO applications use the binary version of DP named *optimal-stopping*, where “stopping” is the exercise of an RO (stop the “wait and see” policy).

DP in continuous time is well discussed in [7, Chapter 4], but these authors use DP for incomplete markets using an exogenous discount rate. Here, we discount with risk-free rate r but use the probability measure Q .

Consider the GBM under Q for the underlying asset V (Eq. 49). We can extend the discrete-time result (see the titled section “The Two Main Derivatives Valuation Ideas”) to continuous time by showing that under Q the correct discount rate for the RO $F(V)$ is r . But initially let μ_F be the discount rate for F under Q . For a small time interval, we

can write $e^{-\mu_F dt} \cong (1 + \mu_F dt)^{-1}$. The waiting (or *continuation*) value is

$$\begin{aligned} F(V, t) &= \frac{1}{1 + \mu_F dt} E^Q [F(V + dV, t + dt) | V(t)] \\ &= \frac{1}{1 + \mu_F dt} \left\{ F(V, t) + E^Q [dF(V, t)] \right\}, \quad (51) \\ &\Rightarrow F(V, t) \mu_F dt = E^Q [dF(V, t)], \quad (52) \end{aligned}$$

where dF can be obtained with the Itô Lemma, but for dV following a GBM under Q measure. Substituting Equation (49) for dV into Equation (23), taking expectations under Q , and noting that $E[dz] = 0$ we get

$$E^Q [dF] = \left\{ (r - \delta)V \frac{\partial F}{\partial V} + \frac{1}{2} \sigma^2 V^2 \frac{\partial^2 F}{\partial V^2} + \frac{\partial F}{\partial t} \right\} dt \quad (53)$$

Substituting Equation (53) into Equation (52) and rearranging, we get

$$\frac{1}{2} \sigma^2 V^2 \frac{\partial^2 F}{\partial V^2} + (r - \delta)V \frac{\partial F}{\partial V} - \mu_F F + \frac{\partial F}{\partial t} = 0. \quad (54)$$

But we know that Equation (32) gives the nonarbitrage relation between F and V . Comparing Equation (54) with Equation (32), in order to get an arbitrage-free price for F , the correct discount rate for F under Q is the risk-free discount rate, that is, $\mu_F = r$. This analysis extends the result obtained in discrete time (recall discussion on Eq. 14).

Another way to solve the perpetual RO problem is by the integral method. Suppose $P(t)$ is the price of a commodity that follows a GBM. Assume that the unitary operational cost C and the investment I to get a plant producing $Q(t)$ are deterministic. Let t^* be the first time that $P(t)$ hits the threshold P^* where the option exercise is optimal. The RO value can be written as

$$\begin{aligned} F(t = 0) &= E^Q \left[\int_{t^*}^{\infty} e^{-rt} (P(t) - C) Q(t) dt \right] \\ &\quad - E^Q [e^{-rt^*}] I. \quad (55) \end{aligned}$$

The integral method has been used in *real option games* [7, pp. 309–314] and in general perpetual options [26]. It uses conventional optimization (below) and some results like (for proof, see Dixit and Pindyck [7, pp. 315–316])

$$\mathbb{E}^Q \left[e^{-rt^*} \right] = \left(\frac{P}{P^*} \right)^{\beta_1}, \quad (56)$$

$$\mathbb{E}^Q \left[\int_0^{t^*} e^{-rt} P(t) dt \right] = \frac{P}{\delta} \left[1 - \left(\frac{P}{P^*} \right)^{\beta_1 - 1} \right], \quad (57)$$

where P follows a GBM. Equation (57) is useful for solving Equation (55) because the integral with integration limits from t^* to ∞ can be written as the difference of two integrals, one with integration limits from 0 to ∞ (it is a perpetuity with growth rate $= \alpha$ and discount rate $= r$) and other with limits from 0 to t^* . The dividend yield for commodities is interpreted as convenience yield and estimated from future markets [12, pp. 182–184].

The classical perpetual RO case of investing I to get the project with value V uses Equation (56) (with V instead P) and the first-order condition (FOC: $\partial F / \partial V = 0$ at V^*) to solve the maximization problem

$$F(V) = \max_{V=V^*} \mathbb{E}^Q \left[e^{-rt} (V - I) \right]. \quad (58)$$

The optimal V^* is nonrandom, but given V^* , t^* is random, so

$$F(V) = \mathbb{E}^Q \left[e^{-rt^*} \right] (V^* - I). \quad (59)$$

There is a trade-off in choosing V^* : if we choose a very high V^* , $(V^* - I)$ will be large, but it will take much time to hit V^* so that $\mathbb{E}^Q[\cdot]$ will be small; whereas if we choose a small V^* , $\mathbb{E}^Q[\cdot]$ will be large, but $(V^* - I)$ will be small. With the FOC in Equation (59) we get V^* [26]. With Equation (59) we get $F(V)$, which is the same expression obtained before (Eqs 38 and 44).

A practical approach for RO using the change of measure concept is the *Monte Carlo simulation* (MCS) of risk-neutral stochastic processes combined with an optimal decision rule. For European options it is simple,

because the rule is easy to set, for example, $F(T) = \text{Max}[V(T) - I, 0]$. The European RO value is

$$F(t=0) = e^{-rT} \mathbb{E}^Q [\text{Max}[V(T) - I, 0] | V(0)]. \quad (60)$$

By simulating the risk-neutral process for V at $t = T$, starting from $V(0)$ at $t = 0$, and using Equation (60), we get the RO value $F(t=0)$. MCS is useful mainly for the case of *many stochastic variables* following correlated stochastic processes, which are easy to simulate but hard to solve using differential equations or lattice methods (the *curse of dimensionality*).

Many ROs can be viewed as a *sequence of European options*. For example, a *multivegetable biodiesel plant* has the option to use soybean, cotton, castorbean, pinion, or palm at each quarter. We simulate the correlated risk-neutral stochastic processes for these vegetable prices and at each quarter we choose the vegetable that provides the maximum profit in that quarter (including the option to stop production). At each quarter, one European option of this kind is expiring. Because the switch-cost is negligible, we can value this plant as the sum of a sequence of European options.

MCS can also be used for *American options*. But the optimal decision rule is not simple as in the European case because of the earlier exercise possibility. In cases with more than three stochastic variables, it can be the best practical way to get the RO value. Since the 1990s some methods for using MCS with American options have appeared. One very popular method is the use of *least square approach* [27] to estimate the waiting (continuation) value, so that this value is compared with the immediate exercise at each t .

Another way is the *evolutionary real option approach* [28], for example, by using genetic algorithm to evolve a population of optimal decision rules (e.g., a threshold curve) and using risk-neutral simulations (and discounting with r) to evaluate the decision rules. The more valuable decision rules are selected as parents of a new generation of decision rules, which are again evaluated with MCS. When the gain in the last

generation for the best rule is small, the program stops and we get a *near optimal* solution with the associated RO value. This approach is computationally very time consuming, but its simplicity makes it a good practical alternative for future complex problems.

OTHER REAL OPTIONS, ISSUES, AND CONCLUDING REMARKS

There are many open questions that demand additional research in ROs. Some of them are listed here.

The effect of strategic iterations of competition and cooperation, when the exercise of an RO by one agent has an impact over the RO of another agent, is an important topic requiring models that integrate RO theory with game theory [16,29,30].

Most RO models assume *complete markets* at least as an approximation. When the market is complete, the martingale measure Q is unique (*fundamental theorem of asset pricing*: [31, Section 19-2]), but when the market is *incomplete*, there are *multiple martingale measures (range)* that can be used for pricing without producing arbitrage opportunities. In this case, it is necessary to select a measure Q from this range, and some *preference theory*, like the investor's *expected utility*, is used to select a value from this range. Exponential utility function has been used in articles on ROs [32,33] when incomplete market arises because the investor is not well diversified so that the private risk is not eliminated by diversification. A simple approach for incomplete markets is to choose the dynamic programming framework with an exogenous discount rate as in Dixit and Pindyck [7], but perhaps some preference theory could be used.

Technical uncertainty even with diversified investors is another topic that demands more research in ROs. For example, the uncertainty with respect to the existence, volume, and economic quality of petroleum reserves is very important for oil companies that have learning options to evaluate. Another relevant application is the R&D project. Methods in which learning is modeled as a *process of variance reduction*

indexed by events (not time) [15], where *events* are the exercise of learning options, and models incorporating *learning measures* [34] are promising paths. RO models incorporating both strategic interaction and technical uncertainty [35] are another topic for research.

The main drawback of an RO is its higher complexity compared to DCF, which demands the identification of the relevant options, modeling of the relevant uncertainties including the best approximation of market values for the input parameters, and optimization under uncertainty algorithm or software. This generates many different ways to apply the key RO ideas and the problem of many different RO values for the same real-life application. For a discussion on the known (but limited) ways to implement the ideas in some popular RO models, see Borison [36] and Copeland and Antikarov [37]. The strength of an RO is its strong conceptual background, but a wider use of ROs is expected.

In this article, the two main calculation concepts used in almost all RO solution methods, the construction of a risk-free portfolio and the change of probability measure, were presented. The article showed the application of these concepts in both discrete and continuous time. As a matter of fact, it is possible to use other methods such as the intertemporal CAPM to solve RO problems [38], but these are rarely used. There are many challenges in developing more realistic RO models, but at the same time they should be simple enough for practitioners. However nowadays RO is considered as a consolidated approach for capital budgeting decisions.

CALL CENTER MANAGEMENT

VIJAY MEHROTRA
THOMAS A. GROSSMAN
School of Business and
Professional Studies,
University of San Francisco,
San Francisco, California

DOUGLAS A. SAMUELSON
InfoLogix, Annandale, Virginia

A call center is an organization where agents of a company talk on the telephone to customers or potential customers. Call centers are central to operations for a broad range of businesses, including travel reservations, product support, help desk services, order taking, emergency services dispatch, and financial transaction processing. Call centers are a strategic asset which provides firms with a direct line to customers, drive customer perception of quality, and generate significant numbers of transactions.

Call centers are a large global industry. It is estimated that for 2008 the United States had approximately 47,000 call centers and 2.7 million agents; Europe, the Middle East, and Africa together had 45,000 centers and 2.1 million agents; and Canada and Latin America had 35,000 centers and 730,000 agents. The demand for agents in India is predicted to exceed one million and there is a shortage of qualified labor.

Call center terminology originated in the traffic engineering work of Erlang [1], and can be different from queueing theory terminology (see the section titled “Queueing Theory and Queueing Networks” in this encyclopedia). Call center managers use “Erlang B” and “Erlang C” to refer to the M/M/s/s (see *The M/M/s Queue*) queues, respectively, and use the dimensionless unit “Erlangs” to refer to “offered load” (or equivalently “traffic intensity”) = arrival rate/service rate.

Call centers can be inbound call centers (which answer calls from customers), outbound call centers (which originate calls to customers, generally for telemarketing

purposes), or “blended” centers that do both. For inbound call centers, call volume and duration are random variables whose parameters and distributions are often estimated from historical data. These estimates are used to determine staffing levels and agent schedules. In contrast, outbound call center managers decide the pace and volume of calls that are placed to customers based on the number of available agents as well as the estimated likelihood of reaching a customer once a call has been placed.

Advances and cost reductions in information technology and telecommunications are creating new call center management approaches. For example, large call center operations are often housed in multiple locations and managed as a single virtual call center. In addition, a rich workflow is possible, including call-specific routing across agents and physical sites, automated interactions with customers on hold, and call messaging that results in an automatic callback to a customer when an agent becomes available. Call center operations are routinely outsourced to third parties. Call centers can be located around the globe to access specialized or less expensive labor resources.

There are several recent survey papers. Aksin *et al.* [2] discuss the business and operational issues facing call center managers, and highlight gaps between industry practice and the operations research literature. Gans *et al.* [3] cite 164 papers associated with call centers and an expanded on-line bibliography [4] includes over 450 papers along with dozens of case studies and books. There are also more specialized surveys. Koole and Mandelbaum [5] focus on queueing models for call centers. L’Ecuyer [6] focuses on optimization problems for call centers. Koole and Pot [7] and Aksin *et al.* [2] focus on multiskill call centers. Human resource issues are important to call center managers but tend to be missing from call center models; Holman [8] and Aksin *et al.* [2] discuss human resources in call centers.

Significant nonpublished call center research and application is performed by consulting firms, services research firms, and software vendors. There is a need for more public-domain work.

INBOUND SYSTEMS

Inbound call centers are driven by random customer call arrivals, usually to a telephone number that is free to the caller. In the simplest situation, a customer is routed to an available agent or, if no agent is available, the customer is routed to a hold queue. After some period, the customer is connected with an agent and speaks to the agent for some random time until the call is completed. It may not be so simple. The customer may encounter a busy signal and be “blocked.” The customer may abandon the hold queue by hanging up upon entry or after a period of waiting. After speaking to an agent, the customer might be transferred to another agent or queue for further assistance. The customer’s problem might not be resolved, leading to a follow-on call in the future. A good general business overview of inbound call center management is Cleveland [9].

Inbound call center managers need to balance cost with service quality. Cost is easy to measure. The largest expense is people, and cost performance is typically measured by agent utilization. Agent costs usually comprise 60–80% of a call center operating budget. Telecommunications costs can be an issue when telephone charges are high and queues are long.

Service quality is hard to measure. Customer waiting time in the hold queue has traditionally been used as a proxy for service quality. Waiting times vary across customers; hence, metrics are a function of the waiting time distribution. The two most popular metrics are average speed of answer (ASA), the mean customer waiting time; and service level (SL), the percentage of calls answered within a target time.

Researchers and call center managers are starting to focus on customer renegeing, also called *abandonment*. The customer abandonment rate (CAR) is becoming an

important metric. Abandonment leads to perverse incentives. Customers who abandon the queue are likely dissatisfied with the service encounter, which is bad for business. However, when a customer abandons the hold, queue shrinks, which is good for the call center’s waiting time metrics [10].

Metrics based on waiting time and abandonment measure a customer’s experience *prior* to service. There is growing interest in metrics for the quality of the customer’s experience *during* service, and the quality of service delivered by individual agents and agent groups. Hence, call centers are starting to use the “first call resolution” metric as well as traditional customer satisfaction surveys.

Creating Agent Schedules

In day-to-day operations, inbound call centers are managed using short-interval (15–60 min) “time blocks” for forecasting call arrivals and scheduling agents. Managers must staff each time block to assure adequate service quality without incurring excessive cost. This difficult managerial and technical problem seems first to appear in the literature in Edie [11], who examined toll booths.

With details varying across call centers, a five-activity process is used to schedule individual agents: (i) “forecasting” to predict call arrival rates by time block; (ii) “performance estimation” of key metrics given alternative agent staff levels by time block; (iii) “staffing” to determine the desired agent staff level by time block; (iv) “shift scheduling” to devise a set of multi-time block agent shifts that in aggregate approximate the desired agent staff level in each time block, considering legal, contractual, and customary work rules; and (v) “rostering” to assign individual agents to shifts, considering work rules and individual agent preferences. Each of these activities has an associated research area and there are interactions across them.

Activity 1, Forecasting. Standard forecasting techniques (see the section titled “Forecasting Techniques” in this encyclopedia) such as Winters’ Method, ARIMA, and regression are widely used for forecasting call arrival rates. However, Gans *et al.* [3] assert

that call forecasting was “still in its infancy.” Challenges specific to call centers include the small size of the time blocks (making the data noisy); the need for a forecast of each queue in a multiqueue center; complex call patterns, demand spikes, and lag effects that may occur at random or without the same effect every time they occur; and the effect of lost demand (abandoned and blocked calls) on future arrival rates. In addition, there will be opportunities for intraday forecast updating.

Brown *et al.* [12] feature arrival rate forecasting models as part of a much larger empirical study of call center operations. Channouf *et al.* [13] test a variety of forecasting models to predict incoming phone calls for an emergency medical system. Taylor [14] empirically study a range of forecasting methods and concludes that there is no clear winner because different methods proved to be more effective under different lead times and workloads. Weinberg *et al.* [15] propose a model for forecasting Poisson arrival rates for short time blocks, which is valuable from an operational perspective.

Avramidis *et al.* [16] discuss the correlation of call volumes across periods of the same day and suggest that information about call volumes in early periods can be used to improve the quality of forecasts for subsequent periods within the same day. Shen and Huang [17] develop a model based on singular value decomposition that is more accurate than standard industry practice and has certain advantages over Weinberg *et al.* [15], while also providing the capability for accurate intraday forecast updating.

Activity 2, Performance Estimation. Performance estimation computes the value of key performance metrics for alternative agent staff levels in each time block. Metrics can be customer-oriented, for example, ASA, SL, and CAR. Metrics can be cost-oriented, such as average agent utilization. Metrics are typically estimated using analytic models or discrete-event simulation.

The simplest situation is a single queue of homogeneous calls handled by homogeneous agents. The standard approach is to model call arrivals as a time-dependent Poisson process (*Poisson Process and*

its Generalizations) with arrival rates determined by the forecasting activity; to model service times as exponential with the service rate forecasted based on historical time-dependent averages; and to use the M/M/s steady-state waiting time distribution (see *The M/M/s Queue*) to determine ASA or SL. This “Erlang C” model is widely deployed in software used by managers with no knowledge of operations research via spreadsheet tools and small stand-alone products. The Erlang C is embedded in virtually every commercial call center resource planning system.

However, the application of the Erlang C model to call centers is problematic for many reasons, including abandonment; complex routings; random arrival rates; and violations of the steady-state assumptions of queueing theory due to short time blocks with block-dependent arrivals and staffing levels [18].

Palm [19] and more recently Mandelbaum and Zeltyn [10] have developed the Erlang-A model to help determine the waiting time distribution as a function of arrival rates, service rates, staffing levels, and the distribution of the time until customers choose to abandon. Random arrival rates are observed empirically by Avramidis *et al.* [16], Brown *et al.* [12], and Steckley *et al.* [20]. They conclude that in the presence of random arrival rates, the Erlang C systematically overestimates waiting time because the assumption of Poisson arrivals with a known arrival rate understates the variability of the call arrival patterns.

Modern call centers can route calls among multiple queues. A common approach is “skill-based routing,” where multiple types of incoming calls are handled by multiple agent pools, each capable of handling a unique subset of call types. Skill-based routing makes performance estimation much more complex, in part, because call arrivals at each agent pool depends on the staffing of the other agent pools. Discrete-event simulation has often been used to address this situation, as discussed in Mehrotra and Fama [21].

Activity 3, Staffing. Staffing sets the desired number of agents in each agent pool for each time block. Staffing is typically determined by minimizing agents subject to

a performance measure goal, such as ASA or SL. Skill-based routing make staffing more challenging.

When management seeks to obtain relatively short ASA and relatively high agent utilization rates, a simple model of practical value is the “square root safety-staffing rule” first observed by Erlang [1] and later formalized by Halfin and Whitt [22]. This rule stipulates that for sufficiently large R (where R is “offered load” or “traffic intensity” = arrival rate/service rate), staffing the system with $R + \beta\sqrt{R}$ servers will perform well for some parameter β (see Aksin *et al.* [2, Section 2.3] for additional discussion on this rule). Steckley *et al.* [20] propose an alternative method for determining staffing levels in the presence of random arrival rates, where the arrival rate variability is either known or is estimated from empirical data.

Activity 4, Shift Scheduling, and Activity 5, Rostering. Shift scheduling and rostering are challenging for call centers. It might not be cost-effective or even feasible to achieve the staffing activity’s desired number of agents in each time block. For example, it can be difficult to devise a schedule with very different adjacent time blocks. (Note that the number of time blocks can be large: with 15-min time blocks in a 24-h center, there are 96 time blocks to be managed.) Creating shift schedules that meet target requirements; satisfy legal, contractual, and customary work rules; and do not lead to the under-utilization of agents is an inherently complex problem. Considering individual agent preferences is also difficult. These topics are discussed in *Tour Scheduling and Rostering* and *Nurse Scheduling Models*.

Integration of the Five Activities. It is a common practice to perform each of the five activities in the staffing process sequentially and independently from the others. However, separating these activities can cause difficulties since, for example, highly variable staff requirements can make shift scheduling more difficult. Integration of these activities is an emerging research theme [2].

In the context of skill-based routing, Avramidis *et al.* [23] show that separating the staffing and scheduling steps can lead to very poor solutions and propose an integrated solution that performs well. Cezik and L’Ecuyer [24] propose a scheduling methodology that combines staffing optimization with skill-based routing using linear programming and simulation, while Fukunaga *et al.* [25] describe a commercially implemented technique that combines artificial intelligence with simulation.

OUTBOUND SYSTEMS

In outbound systems, a computer automatically dials calls and routes them to agents. Typically, the computer predicts when agents will become free and dials in anticipation of agent availability, thereby reducing the time agents wait for the dialed party to pick up the phone or to not answer. The system automatically processes busy signals, no-answers, and telephone company messages.

A key analytical challenge is to determine the “pacing,” or when to dial the next outbound call. If the pacing is too slow, agent time is wasted. If the pacing is too fast a called party answers when no agent is available, creating a nuisance for the called party and a wasted expense for the system.

Research in this area is mostly proprietary and there is scant research literature. The first US patent based on queueing theory [26] was granted for a method [27] that estimated service durations, times from dialing to answer, and proportions of dial attempts that result in answers and synchronized dialing attempts to finish shortly after predicted agent service completions. Other patents, such as David [28], expanded and extended this approach, and there at least 48 additional patents in this area.

Two interesting problems merit research. First is pacing for multiple campaigns, in which some agents may be shifted among different calling campaigns in real time. Second is pacing for systems, in which the called party is switched to a recorded message then back to a live operator; this approach is popular among some charitable organizations that

use celebrity fund-raising appeals, and debt collectors who want proof of what they said.

Blended Systems

Blended call centers allow agents to be switched in real time between inbound and outbound calls. Bhulai and Koole [29] present a queueing theory model which yields a threshold policy for assigning agents to outbound calls. Deslauriers *et al.* [30] provide a set of Markov chain models for a call center where outbound agents can be diverted to serve inbound calls. A few patents, notably those by Szlam *et al.* [31] and Villena *et al.* [32], address aspects of these systems. Call center managers believe that frequent switching between inbound and outbound calls degrades agent performance for both types of calls, and common practice is to make reassignments for blocks of time rather than call by call.

OPERATIONAL TRENDS AND RESEARCH OPPORTUNITIES

Some traditional call center assumptions are being questioned in the operations research literature [2]. One approach is to replace the standard point-forecast of arrival rates for a short time block with a stochastic forecast. It is possible to relax the assumption of independent time block call arrivals and model correlation of arrivals across time blocks. More general assumptions on arrival rates can affect the scheduling and rostering problems, with Steckley *et al.* [20], Robbins [33], and Gans *et al.* [34] taking some early steps in this area, but there are still significant research opportunities. Bassamboo *et al.* [35] propose a methodology for capacity planning and dynamic system control in the presence of random arrival rates and multiple inbound call types.

Scheduling

Call center workforce scheduling decisions can be dynamic. As updated data on call arrivals and agent availability become available over time, short-term forecasts and agent schedules can be adjusted. Mehrotra

et al. [36] have developed a methodology for intraday forecast and schedule updating, while Gans *et al.* [34] have suggested a stochastic programming model with recourse to account for both random arrival rates and intraday schedule updates. However, there are still significant research opportunities.

Use of Real-Time Data

Call center models generally assume that agents' service times are identically distributed for a given class of customer. Outbound models generally assume that the proportion of called parties who answer changes relatively smoothly. However, actual call center data indicate persistent difference among agent service times, even for probabilistically identical customers, and runs of high or low proportions of good contacts and of live answers. Therefore, using real-time data to adjust call center operations could produce improvement in performance, although call center managers are quick to point out that efficiency must be balanced against robustness.

Research Data

Researchers who wish to test their models need data. Data tend to be aggregated into time-based averages, which is problematic from a queueing science perspective. Fortunately, the DataMOCCA Project [37] provides a clean source of high-granularity, call-based customer call data from several sources.

Call Routing

Skill-based routing, in which different agents are capable of handling different subsets of calls in an environment with multiple call types, is a major trend in the call center industry, as discussed in L'Ecuyer [6]. These systems route customers to different agents depending on their needs and support the creation of a hierarchy of agents with highly skilled (and highly paid) personnel handling only the most challenging calls. In the past decade, there have been a number of patents in this area, notably Crockett and Leamon [38]. There is an opportunity for

research regarding design and appropriate performance measures in such systems, and in the dependency and interaction among staffing, scheduling, and routing.

When there are multiple types of calls and multiple types of agents, performance modeling, staffing, scheduling, and rostering problems all become significantly more complex, which leads to many interesting and important research problems such as those addressed by Fukunaga *et al.* [25] and Avramidis *et al.* [39].

Resource Acquisition

Call center resource acquisition is an emerging area of interest. There is a need for additional research on long-term forecasting, personnel planning for general multiskill call centers in the presence of both learning and attrition [40], and for complex networks of service providers [[2], Section 2.2].

Companies routinely outsource call center operations to third party service providers. Hasija *et al.* [41], Ren and Zhou [42], and Milner and Olson [43] explore issues associated with establishing and managing these relationships.

From Call Center to Customer Contact Center

Some call centers are transforming into customer contact centers, which integrate telephone calls with callbacks and voice mail, as well as with email, internet chat, and web-based voice. Customer contact centers face challenges similar to call centers in balancing cost with quality of service, and must grapple with the challenges of predicting customer contact volumes, and scheduling people to communicate with customers. However, from an operations management perspective, such multichannel centers provide additional operational challenges and research opportunities as touched on in Deslauriers *et al.* [30].

ISSUES FOR OR PROFESSIONALS

The highest call center expense is direct labor, so managerial attention is most readily available for techniques that reduce

call volumes, shorten talk time, or improve workforce scheduling. It can be challenging to sell stand-alone operations research (OR) software solutions because call center managers need systems to work together. It is widely accepted in the industry that software sells on the basis of workflow, not algorithms or mathematical models. Thus, “hard” OR innovations need to be embedded in software integrated with the existing call center systems. These systems capture and process data from the ACD and other sources to provide analysis and decision support and to generate workforce schedules. Leading call center management software packages that include or interact with OR techniques include Nice/IEX, Verint/Blue Pumpkin, Genesys/Alcatel–Lucent, and Aspect Telecommunications. There are many minor software vendors.

Certain “OR process” skills and the technique of call content analysis, which prevents future calls by using customer complaints as a driver to improve products, manuals, help facilities, websites, and agent training, can be powerful tools for OR consultants working in the call center space [44]. Researchers in the field of services marketing bring a behavioral science perspective to studying service operations, and pose a set of research questions about call centers that are different than the operations research community; see Bitran *et al.* [45] for more on this emerging area.

CAMPAIGN ANALYSIS: AN INTRODUCTORY REVIEW

JEFFREY KLINE

WAYNE HUGHES

DOUGLAS OTTE

Operations Research Department,
Naval Postgraduate School,
Monterey, California

“As for military methods: the first is termed measurement, the second, estimation [of forces]; the third, calculation [of numbers of men]; the fourth, weighing [relative strength]; and the fifth, victory. Terrain gives birth to measurement; measurement produces the estimation [of forces]. Estimation [of forces] gives rise to calculating [the numbers of men]. Calculating [the number of men] gives rise to weighting [strength]. Weighting [strength] gives birth to victory.” Sun Tzu, *The Art of War*

Deriving insights in military operations through analytical methods is as old as the writings of Sun Tzu, such as the 2500-year-old book *The Art of War* [1]. Discussing considerations for military force disposition, Sun Tzu demonstrates the use of quantitative thinking in military decision making. His writings show that campaign analysis is far older than the origins of operations research in World War II, or Lanchester’s derivation of force-on-force exchange equations from World War I. Broad in nature, campaign analysis is a field of application, rather than a focused academic discipline. Hughes defines campaign analysis as a study of conflict between heterogeneous forces in a series of encounters, over time and a wide geographic area [2]. Its purpose is to develop insight into relationships between risk(s) engaged, resources committed, and campaign analysis. While borrowing from tools of operations research, campaign analysis is simultaneously informed by analogous conflicts in history, geographical literacy, awareness of dynamic social issues and economic interdependencies, and respect for operational military experience. Value is provided to

military decision makers when campaign analysis inspires focused discussion of synthesized information while offering informed, quantitative, specific, yet incomplete advice. *An appreciation for levels of risk versus resources is one product of campaign analysis, but detailed predictions of outcomes are not.*

While the focus of campaign analysis is on quantitative insights in support of operations before and during conflict, the analyses of past campaigns are a vital element of the field that provide guidance, data, and models for present applications. Models and lessons from McCue’s *U-boats in the Bay of Biscay* have application in antisubmarine operational plan (OPLAN) development today [3]. Likewise, Morse and Kimball’s *Methods of Operations Research* chapter on strategic kinematics provides useful models and data developed from their World War II analyses [4]. Additionally, analyses of past campaigns provide tools like Lanchester force exchange equations and Hughes’ naval salvo equations [5]. *Numbers, Predictions, and War* by Colonel Trevor Dupuy is another example of historical data analysis that gives insight into exchange rates between the competing forces [6]. Derived from analyzing historical campaigns, these works are used to help design and adjudicate war game interactions, improve combat simulations, and compute exchange and delivery rates between the conflicting forces. *In campaign analysis, we use the past to inform the future.*

The rest of this article discusses a campaign analysis process and its elements, where analysis has been informative in past campaigns, how campaign analysis is used today, and how it is evolving for future work.

CAMPAIGN ANALYSIS PROCESS

Campaign analysis cannot predict outcomes with assurance. We start with messy, complex problems; rely on performance estimates for most of our data; and deal with complex, dynamic activities, where

opponents have multiple courses of action from which to choose. The analyst's hope is to identify patterns of activity and isolate important conditions for a desirable campaign outcome.

Like most systems analysis studies or detailed operations research models, campaign analysis may be viewed as an IF-THEN statement with feedback loops. *If* we accept these assumptions; *if* we use these data about friendly and enemy forces, weapons, and their dispositions; *if* we select these variables to study; and *if* we use these models; *then*, we obtain results in our campaign, or revisit our original assumptions, data, and models and revise our battle plans.

William "Forrest" Crain describes several general approaches to theater campaign analysis that parallel military staff planning [7]. The first of these is to start at the desired end state of the campaign's objectives, and then plan and analyze back in time to develop conditions and actions that will allow that end state to be achieved. The next approach is to analyze alternatives within bounded sets defined by feasibility, suitability, and acceptability. Similarly, the final approach is to develop and analyze a single best course of action to achieve the desired end state. All variations of campaign analysis are essentially a systems analysis process. A campaign's objectives, concept of operations, and measures of effectiveness are identified; assumptions about the battle environment, force capabilities, and dispositions made; important variables identified; models selected and implemented; results analyzed and evaluated; sensitivity analysis conducted; conclusions warranted by results, and reports delivered to the commander and planning staff.

The campaign's objectives come from the direction provided by political and military leadership at the national level. Derivation of a concept of operations to achieve those objectives, and metrics to measure their achievement, is done in collaboration with the commander and his or her staff. Assumptions are agreed to and provide a bound on the analytical study. We must assume some enemy objective and capability in a region of conflict—and the weather conditions or

season—often making statistical simplifications that we know are not strictly true, such as the independence among probabilities. A common and valuable study output is the identification of critical assumptions or those assumptions whose change would modify our advice to a commander. These critical assumptions may potentially define initial conditions for the commander to establish before campaign execution, such as the type and disposition of his forces, and the security of his sustainment pipeline.

Data are difficult and suspect. Peacetime test data are only estimates of combat performance in a particular future situation and condition. Sensor performance, weapons' effectiveness, platforms' combat range, weapons' load out, and turnaround times are just a few examples of purported "data" that can quickly degenerate from "facts" to assumptions. An estimate or probabilistic distribution, however, is required for each friendly and enemy capability, if only as a first-order approximation. In addition, although we can control (somewhat) the levels, capacities, and disposition of our own forces, the enemy's performance data must be an educated guess, pieced together from intelligence estimates and our assumptions about his objectives. The analyst will mark these estimates for later sensitivity analysis to evaluate which assumptions are critical to the results.

While assembling imperfect, but sufficient inputs, we concurrently select a model or series of models to represent the campaign environment. Broadly speaking, models bound the campaign in either a series of engagements (pulses of power) or a continuous operation where many small engagements create a larger effect (cumulative warfare). The battles across Europe in World War II represent a series of engagements, while insurgent warfare, submarine warfare, and blockades are examples of the continuous cumulative model. Model selection is informed by the scenario and rough concept of operation outlined by the commander and staff.

Model categories range from closed-form probabilistic equations, computer simulations, optimization, and war games

to field experiments and operational rehearsals. A field experiment, the rehearsal of an amphibious landing or coordinated air strike, is a model in the sense that it is not reality. In his book, *The Stress of Battle*, David Rowland observes that ground “combat” on an instrumented range can differ from (exceed) casualty generation rates in similar real battles by a factor of 2 or more [8]. Real bullets are more serious to soldiers than “death” by laser in training. This is an example how actual battle data can inform our modeling efforts.

Various models may be used at each stage of the combat analysis. For example, a war game may help to develop concepts of operation and employment for the opposing sides. The war game’s interactions may be adjudicated by tactical simulations, equations, historic engagements or professional judgment. Once an employment concept or course of action is generated, it may be programmed in a larger campaign simulation to conduct analysis on many model variations. Optimization may be used to analyze the best resource allocation for particular courses of action. This implies some set of campaign measures of effectiveness, agreed to by the commander, to guide planning and evaluate the model outputs, and requires constant dialog between the commander, the planning staff, and the analyst. The dialog also facilitates matching the model’s metrics to those collected during the campaign’s execution, thereby better informing determinations regarding progress toward campaign objectives. In the Battle of the Atlantic in World War II, the exchange rate—merchant vessels sunk per submarine sunk—was popular, convenient, clean, and easy to measure. However, as was pointed out by historians, the “true” measure of accomplishment was successful merchant transits; pushing shipping safely across the ocean was aided by slowing or pinning down the U-boats, without actually sinking them.

Models may be used in a hierarchy representing an extended combat process. The results of engineering-level models on weapons’ performance (e.g., radar performance against an enemy missile) may provide data to an engagement model that

focuses on a single contest between an air defense system and enemy missiles. The engagement model’s output may then be used in a mission-level model that represents the effectiveness of the air defense mission in a particular area. The mission-level output, in turn, can feed a campaign-level model to provide an estimate of air defense’s contributions to the total campaign.

Once the models’ outputs are received, the campaign analyst’s art is tested to its utmost. Interacting with the commander and staff, the campaign analyst must identify important messages from the models’ output that affect the campaign, possibly repeating some of the modeling to identify critical assumptions affecting the results. He/she must evaluate the quantifiable output based on his/her own operational experience and tailor the advice using other considerations, such as the social and economic conditions, or historical regional tensions. This last step is a final dialog between the combat analyst, staff, and commander. The analyst must present his/her contributions in relevant and understandable, jargon-free ways. But successful communication requires a commander’s astute appreciation of campaign analysis in both its power and limitations. *In the end, the value of the campaign analysis is judged by its contribution in aiding the commander to develop his/her intent, strategy, and operational course of action.*

CAMPAIGN ANALYSES’ CONTRIBUTIONS TO MILITARY JUDGMENT

A superb reference on analytical techniques for insurgent warfare, Lieutenant General Julian Ewing and Ira Hunt’s book, *Sharpening the Combat Edge, the Use of Analysis to Reinforce Military Judgment* [9], relates how analysis was used to guide operations during the Vietnam War. The book’s title conveys a balanced message on the contributions campaign analysis can make to planned and ongoing operations. Campaign analysis can reinforce or challenge military judgment, but never replace it. We illustrate with three examples from World War II where analysis was used to shape and reinforce strategic planning or ongoing operations.

In 1938, German submariner Admiral Doenitz was asked by the German high command to estimate the number of undersea boats (U-boats) he would need to cut off transatlantic supplies from North America to Britain when war began. To obtain such a figure, the Admiral and his staff employed war gaming to estimate the tonnage of allied shipping to sink to starve Britain's need for fuel, ammunition, war supplies, and food. Their estimate of 600,000 tons per month was undoubtedly based on assumptions of the intensity of future land and air combat with corresponding supply requirements; allied shipping capacity, speeds, and resupply rates; merchant crew availability; and British shipping replacement rates [10]. To obtain this level of effectiveness, they believed 300 U-boats were needed. Again, assumptions on submarine effectiveness, sea coverage capabilities, and on-station times were considered necessary to derive this number. The German Navy was forced to start the war with only 57 U-boats in 1939. Admiral Doenitz's campaign analysis prior to the war was, in hindsight, probably about right. In any event, it undoubtedly shaped the German Navy's operational thinking during the Battle of the Atlantic [11].

On the other side of the Atlantic, to gain strategic lessons in a potential conflict with Japan, a series of strategic war games was played between the world wars at the United States Naval War College. This campaign analysis used serial war gaming to educate and inform the strategic planners of War Plan Orange—an evolving strategic plan, decades in development. In case of war with Japan, an initial strategy proposed moving the US fleet quickly across the Pacific to engage the Japanese Navy, if Japan moved against the US Philippine territory. After several war games and tactical assessments on the War College's game floors, planners realized that despite the nominal 5:3 advantage in capital ships tonnage enjoyed by the US Navy, too few ships would be in position to conduct an early battle for mastery of the seas [12,13]. The island-hopping campaign to roll back Japanese forces then emerged as a more feasible strategy, and was later executed during the war. In his book, *War Plan*

Orange, Miller relates how planners in Newport and Washington studied logistic requirements and capabilities, force availability, and force-on-force exchange evaluations through capability comparisons, and force buildups to quantitatively update the debate on how to defeat Japan.

Best known to operations research professionals is the birth of their discipline during World War II: England and the United States brought together scientists from diverse fields to develop the best coordination methods of radar and fighter aircraft during the Battle of Britain, and to make valuable contributions to the Battle of the Atlantic antisubmarine campaign. In both cases, scientists evaluated how best to employ new technologies to shape ongoing campaigns. In their seminal work, *Methods of Operations Research*, Morse and Kimball quote Admiral E.J. King, the American Chief of Naval Operations (CNO), regarding operations research contributions to the allies' response to new German submarine technology and tactics: "Operations Research, bringing scientists in to analyze the technical import of the fluctuations between measure and counter-measure, made it possible to speed up our reaction rate in several critical cases" [14]. In the same 1945 report, King makes clear the necessity for scientists to work under the direction of, or have close personal contact with, the military officers planning and carrying out the war. This relationship ensured that mathematical tools developed by the scientists would be influenced by campaign planners in a close relationship of mutual trust. Search theory, tactical analysis, and combat exchange rate equations, refined and evaluated by scientists during the war, are all tools in the campaign analyst's toolbox.

CURRENT USES OF CAMPAIGN ANALYSIS

Force Structure Analysis

Campaign analysis has long been the cornerstone of the US Department of Defense (DoD) staff requirements generation and force structure development. Although many countries use similar processes to establish force requirements, we focus on the United

States defense department as the example most familiar to the authors. Using strategic guidance focused on potential major conflicts and current operations, campaign analysis provides critical insights into capability gap assessments and helps decision makers understand the risk associated with procurement decisions. Currently the analysis generates the foundation of resource decisions within the biannual DoD Program Objective Memorandum. It is conducted within the context of comprehensive joint and combined warfare analysis.

Campaign analysis to support force structure decisions starts with a review of national-level guidance. The DoD's strategic goal is to respond to the security requirements articulated by the President through the National Security Council. The Defense Department translates the strategic priorities of the National Security Strategy into defense documents, such as the Guidance for Development of the Force. Those articulate specific war-fighting capabilities and requirements within a fiscally constrained budget. Defense Planning Scenarios (DPSs) outline analytic baselines by identifying possible future conflicts the United States' armed forces may be required to face. The DPSs establish the future war-fighting baseline, assess force flows associated with each campaign scenario, and attempt to anticipate the combat characteristics of potential adversaries.

Every US armed service conducts its campaign analysis a bit differently, but converting national guidance to force requirements via campaign analysis of the DPSs is the underlying goal for each service. To illustrate, we focus on the Navy's process. The CNO augments national strategic directives with pertinent maritime guidance that focuses campaign analysis on naval contributions to the joint and coalition war fight. In 2007, *A Cooperative Strategy for the 21st Century Seapower*, served this purpose [15]. Signed by the service chiefs of the US Navy, US Marine Corps, and US Coast Guard, it articulates expectations for future operations of maritime forces. Supplemented by the Naval Operational Concept, Navy Strategic Plan, specific CNO guidance, and a

maritime-specific intelligence update, these documents collectively describe activities and associated assumptions for Navy campaign analysis. Merged with the DoD DPSs, they provide the foundation for the Navy's analytical work in force structure analysis.

A maritime, DPS-based analysis is composed of the same steps from the general campaign analysis method previously discussed. Figure 1 shows this procedure for the Navy staff. Within each scenario, the maritime campaign objectives are identified (e.g., protect friendly shipping). Tasks are then assigned to joint forces to obtain that campaign objective (e.g., clear minefields). Campaign metrics are selected and criteria established within the campaign plan (e.g., time needed to restore military and commercial shipping's access into a theater). Finally, specific force contributions to meet those mission criteria are analyzed (e.g., capability to find, fix, and clear the mines). In this way, current force capabilities are assessed to meet future mission requirements.

The practical goal of naval campaign analysis, as conducted by the headquarters staff, is to identify existing war-fighting capability and capacity gaps, or shortfalls, in specific weapon systems and force structure components, which will form future requirements and ultimately affect program budget decisions. Since the analysis is grounded in DoD-approved war-fighting scenarios, which stress all aspects of maritime warfare, the campaign analysis provides a comprehensive assessment of all maritime warfare areas and their interdependencies within the campaign. The individual DPSs test specific war-fighting capabilities such as antisubmarine warfare, strike warfare, and antiship missile defense, as well as theater security cooperation and lesser contingency mission sets. Finally, the war-fighting requirements highlighted in the current analysis are then assessed against capabilities addressed in acquisition programs in previous budget Program Objective Memorandums, to determine potential capability and capacity gaps.

Gap analysis assisted by campaign analysis generally takes two forms. First, it provides insights as to how well our procurement objectives keep pace with the

Figure 1. The scenario-based war-fighting analysis.

enemy's weapons advancements. The gaps can show divergence in the strategic outlook (and, hence, the need for improvement of the forces), focus advancement on a particular enemy war-fighting capability that out-paces our potential technological advancements, or atrophy of a particular war-fighting capability that can be exploited by a potential enemy. Campaign analysis helps quantify the magnitude of the capability gap and shows the propensity of specific technologies to overcome it.

Second, campaign analysis helps to describe the enemy's war-fighting capabilities over time. Our procurement programs may reflect the enemy's buildup or technological advancements, but not at a rate that meets critical parameters of the campaign. Capacity gap analysis is critical in the development of new strategies, such as the need to build partnerships for theater security, as defined in *A Cooperative Strategy for 21st Century Seapower*.

The insights that campaign analysis provides are not complete without concurrently addressing risk assessment. Assessing risk aids the calculus of limited resource allocation decisions. It can help shape

command decisions regarding the primacy of addressing short-term gaps versus providing for future capacity and flexibility.

In summary, the services build their campaign analyses on the foundation of national security guidance and within the context of DoD-approved planning scenarios. Although each service focuses on its domain, these campaigns include the joint and coalition capabilities that the other services contribute. Campaign analysis provides insights into current and future capabilities and force structure requirements, while providing decision makers with the appropriate risk assessments. Joint campaign analysis is the bedrock of resource allocation decisions within the DoD.

Operational Planning and Execution

Campaign analysis also contributes to the development of current OPLANs. The primary difference between analyses to support future force structure planning and current operational planning is that in current OPLAN development, the resources available to the planners and enemy are immediate, not years in the future. Bertha

and Shelton provide general approaches to provide combat operations analysis [16]. For the most part, these parallel the analytical methods already described, but they focus on providing the commander a quantitative assessment of important issues related to resource allocation in time, distance, location, cost, and effectiveness. These broad questions may be developed in advance and identified as the commander's essential elements of analysis, with related measures of effectiveness. If the plan is executed, collecting these measures during the campaign's phases becomes an important way to assess goal achievement.

Campaign analysis is also used during the execution of a military campaign to redirect resources, as the enemy's actions and our own performance impact the original plan. Collecting metrics related to achievement of a campaign's objective, assessing engagement results, and modeling new courses of action are activities conducted by campaign analysts during ongoing operations.

NEW OPPORTUNITIES AND CHALLENGES

When threats and strategies change, new military missions emerge and campaign analysis must develop new tools to provide quantitative contributions to aid decision making. Following the fall of the Soviet Union and accompanying the rise of the terrorist threat, the past 30 years have been a time of ferment. Examples of new missions and resulting technological advancements include expanding interest in social studies, the impact of robotic swarms on the battlefield, the influence of cyber war, and the ability to exploit computing power through data mining.

The US military is invigorating an interest in how civil and constabulary actions by armed forces can shape social outlooks to counter enemy insurgents. These actions may include digging wells, providing security for a marketplace, giving assistance after a tsunami, or intercepting pirates on the high seas. Understanding and measuring the effects of their actions on local population perceptions and attitudes requires an appreciation for local societal norms, invoking the

assistance of social sciences. In some cases, direct measures are too difficult to obtain, so indicators are selected as surrogates. For example, school attendance in a region as an indicator of achieving stability may be selected. By teaming with regional experts, planners, and social scientists, campaign analysts can strive to develop measures or indicators to help quantify the effects of civil interactions. Modeling these effects to obtain quantitative insights is challenging. Human values and attitudes are complex, changing, and not always "rational." Lessons from social sciences, strategic communications, and even advertising may prove valuable in attempts to model issues related to shaping perceptions through civil actions.

With increased capabilities in cyber networking and the potential for numerous unmanned vehicles, regular warfare is becoming more complex. Force-on-force sequential warfare and cumulative warfare have the potential to merge across a wider geographic region, where simultaneous asymmetric engagements may create emerging conditions for victory [17]. This increase in complexity poses a new requirement for the campaign analyst. Casualty exchange models representing either large, sequential engagements or smaller, continuous actions may not be sufficient. Use of agent-based simulation to model each robot or attack vehicle in a basic engagement may provide a better understanding of networked and robotic warfare. Agent-based modeling is not new, but its use to model the effects of emerging technologies in a long campaign is a method that is promising for the future.

"Data farming" aids new simulations by distilling the large databases that are generated. Modern computing power allows many thousands of simulations of a campaign, while varying numerous parameters. Through design of experiments, select parameters can be varied across their possible range. Data analysis estimates the correlation between parameters and potential outcomes. The goal is a better understanding of initial conditions (weapon performance, logistic capability, and geography) required to obtain the desired

campaign objectives. Computing power also allows solutions to new “Attacker–Defender” optimization models that provide planners with the best friendly courses of action, given the enemy may observe our preparations before mounting his most effective defense against us (or Defender–Attacker models, where our defensive preparations may be visible to the attacking enemy). Performance data assumptions can be quickly modified to see how the initial conditions affect decisions by both enemy and friendly forces. For example, best placement of theater air defense platforms to defend a number of cities and military installations may be derived to counter the enemy’s worst-case launch plan, assuming the enemy will observe the positioning of our defensive interceptor platforms. If additional friendly platforms are provided, or if new enemy capabilities are discovered, the optimization can be quickly rerun to change force distribution and see how this may affect overall defender performance [18].

Campaign analysis may also benefit from a more aggressive adoption of system dynamics modeling, which provides the potential to capture a better understanding of the complexity associated with changing conditions and feedback loops in the execution of a campaign. Uncovering possible unintended consequences from our actions and discovering interrelationships within the target system we are trying to affect are two benefits that may be derived. For example, Grynkewich and Reifel [19] used a systems dynamics model to better understand the relationship between time, funding, and operational aspects of the radical Islamic Salafist Group for Preaching and Combat (SGPC) in Algeria. Although, by their own admission, their resulting model had limitations and will benefit from additional research, the act of creating the model provided a deeper understanding of the SGPC’s funding sources and their relationship with radical activities.

CONCLUSIONS

Campaign analysis is an applied field of endeavor designed to provide quantitative

insights to a decision maker on how to best use military forces to achieve strategic and operational goals. Analysis at the campaign level may aid in concept generation and course of action selection. But because of the sheer number of variables and because a campaign is conducted against a thinking, adaptive enemy, it can only supplement, never replace, experienced military and naval judgment. Campaign analysis adapts tools from operations research, social science, and systems analysis. It applies simulation, optimization, data analysis, economics, game theory, statistics, and psychology as well as an appreciation of historical, social, and military experience. In the end, however, the value of campaign analysis is judged solely by its ability to provide the commander with timely, useful, and measurable information to guide decisions.

CAPACITY ALLOCATION IN SUPPLY CHAIN SCHEDULING

Capacity allocation problems arise frequently in manufacturing systems, where one or more manufacturers supply one or more distributors (see **Capacity Allocation**). We adopt this notation throughout, in place of, for example, “suppliers” and “retailers,” since the scheduling costs we consider are most typically incurred by manufacturers and distributors. A capacity allocation problem can be viewed as either (i) a deficiency or excess of capacity allocated to a single-product line or distributor, or (ii) a misallocation of capacity among multiple product lines or distributors. Moreover, a misallocation of capacity can lead to excess capacity in a part of the system and a deficiency elsewhere, resulting in high scheduling cost and poor supply chain profitability. As we discuss, capacity allocation and scheduling issues are closely related, and decisions involving them need to be coordinated.

Capacity allocation problems can originate on either the demand side or the supply side. On the demand side, certain industries naturally experience volatile demand, which makes capacity planning more difficult. Examples include industries with high fashion content or occasional demand surges, and industries with rapid technological development including telecommunications and consumer electronics. The supply side also generates capacity allocation problems, for example in industries that are capital-intensive, where additional capacity

cannot be added quickly in order to meet demand. Capacity allocation and scheduling problems are more likely to arise in make-to-order environments, where production is stimulated by an order. This is because, in make-to-stock environments, inventory can be used as a buffer to resolve differences between demand and supply. Moreover, it is in make-to-order environments that detailed scheduling is most valuable.

Capacity allocation problems can most easily be discussed in simplified, single-product environments. Although capacity allocation among products is not an issue here, there may be inefficiencies that result from over-ordering or under-ordering, where distributors distort their demand information and orders for their own interests. Capacity allocation issues within multiple product environments are often considered as manufacturing flexibility, which is the ability to use the same capacity to produce different products. Capacity allocation among distributors can be performed either product by product or in total, across all products. There are advantages to each approach. When manufacturers allocate capacity product by product, they more closely control their schedule and therefore also their costs and profitability. The allocation of total capacity across products is preferred by distributors, since it gives them more flexibility. Also, since distributors are closer to the market than manufacturers are, they may have better market information. This can enable them to make more efficient choices about how to use the capacity that is allocated to them.

Capacity allocation problems are often studied in coordination with other operational decisions in supply chains. We focus on capacity allocation decisions within the scope of *supply chain scheduling*, which studies the coordination of scheduling and other operational decisions within supply chains. Within supply chain scheduling, the benefits of coordinating the entire supply chain are evaluated exactly, by using

optimal algorithms. Chen (see *Coordination of Production and Delivery in Supply Chain Scheduling*) and Hall (see *Supply Chain Scheduling: Origins and Application to Sequencing, Batching and Lot Sizing*) provide an overview of the coordination of scheduling and other operational decisions, such as sequencing, batching, lot sizing, and delivery, within supply chain scheduling.

Scheduling is important in capacity allocation decisions because orders from distributors typically specify not only quantities, but also delivery times. Further, capacity is often time-sensitive, so manufacturers incur different scheduling costs under different production schedules. Traditionally, scheduling decisions are made only after production capacity has been allocated. However, with increasing competition and declining profit margins, it is necessary for companies to consider capacity allocation and scheduling decisions simultaneously, especially in make-to-order environments [1]. For example, in the personal computer industry, Dell, Apple, and Gateway have responded effectively to volatile customer demand by

managing capacity and production schedules simultaneously [1].

Capacity allocation problems are often modeled as cooperative or noncooperative games. In Table 1, we classify 20 related works. Our classification scheme focuses on modeling characteristics. In Table 1, the column “Game” shows whether cooperative (C) or noncooperative (N) game theory is used; the column “Capacity” indicates whether capacity is sufficient (S), deficient (D), or both (DS); the column “Product” indicates whether a single (S) or multiple (M) product environment is considered; the column “Scheduling” indicates whether scheduling is considered or not (Y: yes; N: no); the column “Mechanism” shows the mechanism by which capacity is allocated (A: auction; C: contract; P: pricing; R: rule); finally, the column “Truth” indicates, for noncooperative distributors, whether the capacity allocation mechanism finds the same allocation as when all the distributors reveal their true information (Y: yes; N: No; YN: multiple mechanisms with both yes and no). Under “Mechanism,” a rule can be

used for capacity allocation, for scheduling, or for both.

This article is organized as follows: the section titled “Capacity Allocation Mechanisms” reviews the papers listed in Table 1. The middle section presents a list of potential future research directions, and the final section provides a summary.

CAPACITY ALLOCATION MECHANISMS

In the section titled “Cooperative Capacity Allocation,” we discuss cooperative games that involve capacity allocation and scheduling issues. We focus on the existence of fair allocations of savings that ensure the cooperation of all the players. The subsequent section discusses noncooperative capacity allocation games. Some representative works on capacity allocation without scheduling issues are introduced, followed by a discussion about the allocation of scheduling capacity among competitive distributors.

Cooperative Capacity Allocation

Cooperative capacity allocation considers a central planner which finds an allocation of production capacity that achieves an optimized or nearly optimized system value, and then distributes the resulting total profit or cost saving among the manufacturers and distributors in a mutually beneficial way. Thus, we consider a cooperative game where all the players work together in a grand coalition. However, in order for this coalition to be stable, each subset of players must receive at least as much profit as they could obtain independently. Profit divisions that ensure stability of the grand coalition by achieving this are said to be in the core. Core solutions compensate some players for foregoing other profitable opportunities, in order to sustain the grand coalition. In the following discussion, we focus on cooperative capacity allocation games with scheduling costs. An important distinction within the related literature is whether total capacity, if properly allocated, is sufficient.

We first discuss problems where total capacity is sufficient. However, the profitability of the orders, referred to in the scheduling literature as jobs, depends on which part of the capacity is allocated to them, since this determines their completion times. Within this literature, two types of jobs are studied. For preemptive jobs, the processing of a job can be stopped and resumed at a later time; for nonpreemptive jobs, processing cannot be interrupted until completion. In our discussion, jobs are nonpreemptive unless specified otherwise.

The simplest cooperative scheduling games are the sequencing games defined by Curiel *et al.* [2]. Suppose that a sequence of nonpreemptive jobs, without idle time among them, is given. In practice, this is typically the order in which the jobs arrived. Each job incurs a cost that increases linearly with its completion time. Thus, a pairwise interchange of two adjacent jobs may result in cost savings. A sequencing game considers the various possible divisions of such savings. It is shown that divisions which result from dividing the savings equally between the two adjacent jobs are in the core. This valuable insight has led to several generalizations.

The first generalization, by Curiel *et al.* [3], considers cost as a general nondecreasing function of the job completion times. They identify a particular division of savings, and show that it is always in the core. Under this division, the payoff to player i is the average of (i) the incremental value from adding i to the coalition of players that precede i in the initial sequence, and (ii) the incremental value from adding i to the coalition of players that follow i in the initial sequence. The second generalization, by Slikker [4], allows nonadjacent job interchanges. Maniquet [5] discusses a related problem of sequencing agents who require a service. The initial sequence is given by their arrival order, but efficiency requires that they be served in nondecreasing order of waiting cost. An axiomatic justification is given for using the Shapley value to determine the savings division. The Shapley value is the incremental value added when a player joins

a coalition, averaged over all possible joining sequences.

Another natural generalization of the basic sequencing game model allows for no initial sequence, as discussed by Katta and Sethuraman [6]. A single machine is used to process jobs from multiple agents. Each agent has a single job with scheduling cost in proportion to its completion time. A reasonable consideration of fairness is to treat every job equally, that is, to sequence the jobs randomly. On the basis of the definition of the expected cost of a coalition, the authors propose two solution approaches to derive upper bounds on the allocation of the cost of a centralized optimal schedule to any coalition of agents. One of these approaches guarantees a nonempty core, while the other does not.

We now consider works where the total capacity is insufficient. One solution to this is outsourcing, as commonly used in large-scale electronics manufacturing. Aydinliyim and Vairaktarakis [7] consider a group of manufacturers who outsource their operations to a single third party. They describe a closed-form expression for a particular division of savings, and show that it is a core solution of the game. Using this division, the total cost can be reduced by an average of 32%. Cai and Vairaktarakis [8] provide a similar analysis, allowing for preemptive processing. They show that cooperation among manufacturers reduces costs by about 20%. Vairaktarakis and Aydinliyim [9] consider manufacturers which individually subcontract part of their orders, and minimize their total job completion time. The third party's rescheduling solution provides substantial savings, relative to the Nash equilibrium or first-come-first-served solutions. A Nash equilibrium is a solution in which no player has an incentive to change its decisions, assuming that the other players do not. The authors describe a core solution of the game. An interesting insight is that decentralized solutions tend to underutilize third-party capacity, relative to those chosen by a central planner.

Another solution to a total capacity shortfall is the rationing of capacity through a capacity allocation rule. This solution is applied to a two-stage supply chain involving

a manufacturer and several distributors by Hall and Liu [10]. Three steps occur: (i) the manufacturer allocates capacity and a set of orders that can be revised and resubmitted, to the distributors; (ii) the distributors revise their orders to maximize profit, either by coordinating among themselves or not; and (iii) the manufacturer schedules its revised orders, subject to its allocated capacity and resubmittable orders. The distributors' capacity-sharing problem is modeled as a cooperative game. Three coordination issues are studied: first, the manufacturer's coordination of production and capacity allocation, which generates 10.66% more profit on average for the manufacturer than a typical result from the proportional and linear capacity allocation mechanisms [11,12]; second, the distributors' coordination of order revisions, which generates 2.58% more profit for them; and third, coordination between the manufacturer and distributors, which generates 3.44% more profit for the supply chain.

Noncooperative Capacity Allocation

Noncooperative decision environments are characterized by a lack of centralized coordination, imperfect information, and conflicts between manufacturers and distributors. In such environments, it is difficult to find an efficient allocation of capacity, even when scheduling issues are not considered. Capacity allocation mechanisms without consideration of scheduling issues typically use simple allocation rules. Examples include the lexicographic, proportional, linear, relaxed linear, and uniform allocation rules [11,12]. More complex allocation mechanisms, such as a turn-and-earn policy [13], option contracts [14], and pricing mechanisms [15] are also used in practice. When capacity allocations are time-sensitive, scheduling issues arise and make capacity allocation decisions more difficult. In this case, auctions and complex allocation mechanisms help to find well-coordinated solutions for capacity allocation problems. This may require the elicitation of true information from competitive distributors.

We first introduce noncooperative capacity allocation models without consideration

of scheduling costs. An important concern here is strategic ordering. For example, distributors may order more than their ideal requirements, in order to receive larger order allocations. Cachon and Lariviere [11] show that capacity allocation mechanisms using proportional and linear allocation rules are subject to order inflation, whereas those using lexicographic and uniform allocation rules are truth inducing. Strategic ordering increases the manufacturer's profits, but this may be more than offset by reduced profit at the distributors. The net effect on overall supply chain profit tends to be positive when the wholesale price is high, and strongly negative when it is low. Cachon and Lariviere [12] consider two types of capacity allocation mechanisms: those that induce truth telling by the distributors, and those that are vulnerable to strategic ordering. It is shown that truth telling helps the allocation of capacity among the distributors, but may distort the choice of total capacity level.

Capacity allocation schemes based on past sales may benefit manufacturers at the cost of distributors. Cachon and Lariviere [13] consider a manufacturer which sells to two distributors over a two-period planning horizon. Demand in each period has two possible states, high and low. The manufacturer chooses a wholesale price and a capacity level. The distributors choose their order quantities. The authors demonstrate that a turn-and-earn policy based on past sales may benefit the manufacturer more than a fixed capacity allocation scheme based on order size. However, the distributors and the overall supply chain may be less profitable. This occurs because the turn-and-earn policy may induce the distributors to sell more than is optimally profitable when the demand is low, in order to increase their future capacity allocations. The manufacturer may change its wholesale price and capacity level to account for the distributors' increased sales, which can compensate the distributors' and overall supply chain profits. This compensation is sufficient to improve overall supply chain performance, except where capacity is extremely tight.

More complex allocation schemes may also be useful. Fang and Whinston [14] design an

option contract for a supply chain where, from the supplier's perspective, the value of capacity for each retailer is either high or low. The supply chain with the option contract achieves the same expected total return as if the supplier knows the number of retailers of each type before investing in capacity. Ganesh *et al.* [15] develop a congestion pricing mechanism for allocating bandwidth in communication networks. It is shown that there exists a unit price such that if all users predict that price and select their transmission rates accordingly, then the resulting price coincides with the prediction.

The works [11–15] do not consider scheduling cost. However, if capacity is time-sensitive as in many make-to-order environments, additional cost savings are obtainable by including scheduling issues in capacity allocation decisions. As discussed in the previous section, a centralized optimal solution can save up to about 30% of scheduling cost, relative to a typical capacity allocation that does not consider scheduling. Since in many practical situations centralized decisions are not possible, we next consider noncooperative capacity allocation problems that include scheduling issues. A typical assumption that promotes problem solvability is that each distributor requests production capacity that can be modeled as a single order or job, as shown in Table 1, in the column "Product."

We introduce the use of auctions to allocate production capacity, and then discuss examples of mechanisms that seek true information from distributors in order to find a centralized allocation of capacity. Wellman *et al.* [16] consider a capacity allocation problem involving several agents, each with a single job that allows preemption. The agents maximize their profit, which is the value of their scheduled jobs, less their scheduling cost and their cost of purchasing capacity. The facility owner maximizes its total revenue. The authors describe ascending auction mechanisms with two alternative market goods: time slots and time slot bundles. A time slot is a single unit of capacity at a fixed time, and a time slot bundle consists of a set of slots with the last one at a

fixed time. If time slots are chosen as market goods, then an equilibrium solution is globally optimal. It is possible that no equilibrium solution exists, due to the presence of complementarities. Secondly, with time slot bundles as market goods, the system value of an equilibrium solution is sometimes not good enough to be useful in practice. For a similar problem, Reeves *et al.* [17] illustrate the difficulty of making strategic choices in a simple ascending auction game. They show that straightforward bidding policies and their variants can provide capacity allocations that are not close to optimal.

Hall and Liu [18] study a capacity allocation and scheduling problem involving several buying agents and a single facility, where job preemption is not allowed. The objective of each agent is to maximize its profit, that is, its revenue less cost of capacity and scheduling. The objective of the facility owner is to maximize its revenue. Capacity is allocated using one of three market goods: time slots, fixed time blocks, and flexible time blocks. A fixed time block is any block of consecutive time slots that ends at a specific time, whereas a flexible time block is any block of consecutive time slots that ends no later than a specific time. The flexible time block auction typically provides more efficient schedules and better supply chain value than auctions using the other market goods, and on average more than 94% of the profit found by a centralized planning approach. Also, on average, flexible time blocks provide more profit for the distributors, and thus attract more buying agents to bid higher prices. With only a 6% increment in the number of agents bidding, or a 25% increment in bid prices, the facility owner achieves more revenue in the flexible time block auction than in the time slot auction. However, for both the auctions with fixed and flexible time blocks, there may not exist an equilibrium solution that is globally optimal.

Hain and Mitra [19] consider a problem where a manufacturer allocates capacity at a facility to multiple agents, each of which has a single job to process. The jobs have the same scheduling cost function that is publicly known, but a processing time known only to their agents. If the cost function is strictly

increasing and concave, then there exists a mechanism under which truth telling is a best response of an agent whenever other agents are truthful.

Bukchin and Hanany [20] analyze a dispatching and sequencing model where each department has a set of jobs and decides whether to process each job using an in-house resource with limited capacity or using a less efficient subcontractor. The objective is to minimize the total completion time of the jobs. A centralized schedule may not be a decentralized Nash equilibrium schedule. The decentralized Nash equilibrium schedule may not be unique, and finding it is an intractable problem. The ratio between the Nash equilibrium cost and the cost of a centralized optimal solution ranges from 1.00 to 1.35. A coordination mechanism is designed to guarantee that at equilibrium, a centralized optimal solution is found.

Vairaktarakis [21] considers multiple competing manufacturers which outsource their operations to a third-party capacity provider. Each manufacturer decides the amount of its workload to be outsourced, so as to minimize the completion time of its in-house and outsourced workloads. The paper develops pure Nash equilibrium schedules under several production specifications from the third party and information-sharing schemes of the manufacturers. Near-optimal supply chain performance is achieved if the third party chooses an appropriate incentive rule and the manufacturers share sufficient information.

FUTURE RESEARCH

For capacity allocation in supply chain scheduling that involves cooperative players, we propose the following interesting directions for further research:

1. Cooperation and cost sharing between manufacturers and distributors at the capacity planning stage may provide an improvement over uncoordinated decision making where manufacturers make capacity allocation decisions based on the cost of capacity, and

then distributors submit orders after the capacity level is determined (see **Capacity Allocation**).

2. It is valuable to study incentives, stability of cooperation, strategic behavior, and capacity planning within supply chain scheduling (see **Coordination of Production and Delivery in Supply Chain Scheduling: Origins and Application to Sequencing, Batching and Lot Sizing**).
3. It is interesting to extend sequencing games to consider more general scheduling environments and to find implementable cooperative mechanisms. See Refs 4–6.
4. Capacity-sharing games, involving both multiple manufacturers and multiple distributors, deserve careful exploration. See Refs 7–10.
5. Testing whether a given instance has a fair payoff division, and testing whether a given payoff division is fair, have been studied to only a limited extent. See Ref. 10.
6. Cooperative schedule planning games arise when various scheduling resources are owned by different agents. More investigation of such games is needed.
7. It is interesting to study cooperation with limited information sharing. Further, it should be possible to design mechanisms and incentives to encourage the players to release full and true information.
8. General theoretical structures may play an important role in successfully solving a specific game. For example, linear programming and duality have been applied to solve several important cooperative games within supply chains.
9. Several payoff divisions such as the Shapley value, nucleolus, and others, have not been studied extensively within capacity allocation games. Also, desirable properties of fair solutions, such as population monotonicity, should be studied.

10. One important problem is finding weakly fair payoff divisions, using concepts such as the ϵ -core and least core value, when a fair payoff division does not exist.

For capacity allocation in supply chain scheduling with noncooperative players, we propose the following interesting directions for further research.

1. Noncooperative capacity planning games involving multiple manufacturers should be studied. See Refs 11 and 12.
2. Competition between the distributors for demand from all the customers should be studied in the context of capacity allocation games. See Refs 11 and 12.
3. Multiechelon capacity allocation games with inventory-holding distributors model additional practical issues and therefore deserve investigation. See Ref. 13.
4. Capacity allocation with discrimination, either in prices or in capacity allocation mechanisms, or in both, is an interesting topic for future study. See Refs 13 and 14.
5. It is interesting to consider generalized games where distributors place orders that compete for both production capacity and order delivery time. See Ref. 15.
6. Combinatorial auctions are naturally useful for the allocation of discrete capacity and other scheduling resources. Research is needed to develop effective ways of solving the bid determination and winner determination problems. See Refs 16–18.
7. It is interesting to investigate heuristic-based equilibrium for scheduling jobs, due to the intractability of noncooperative scheduling games. See Refs 16–18.
8. It is important to conduct further studies of auctions of scheduling resources, since few practically effective auction mechanisms have been developed. See Refs 16–18.

9. Since it is difficult to predict the strategies of bidders, it is important to design robust auction mechanisms that are insensitive to players' bidding strategies and policies. See Refs 16–18.
10. Opportunities exist for modeling manufacturers' scheduling costs in various relevant ways while analyzing capacity allocation decisions. See Refs 19–21.

SUMMARY

Capacity allocation problems in manufacturing can be studied using both cooperative and noncooperative games. Such problems include under-allocation and over-allocation of capacity, and originate from either the demand or the supply side. Cooperative game models for capacity allocation identify profit divisions that ensure a stable coalition of the players. Recent research suggests various ways in which the extra value or cost saving from a centralized solution approach can be distributed. Noncooperative game models address the problem of strategic ordering, where players introduce false information in order to gain an advantage. Incentives need to be built into the manufacturing system to prevent this. Naturally occurring allocations of capacity often form a Nash equilibrium. However, Nash equilibrium solutions may not be close to an optimal solution for the overall supply chain. Within noncooperative games, auctions offer several useful features, especially the need to share only very limited information, such as a price, with competitors. Auctions need to be carefully designed in capacity allocation problems, since the resulting supply chain performance is highly sensitive to the choice of market goods. Moreover, different measures of supply chain performance recommend different choices for market goods.

CAPACITY ALLOCATION

MARTIN A. LARIVIERE
Kellogg School of Management,
Northwestern University,
Evanston, Illinois

Seldom in life is it always possible to make everyone happy. Supply chains are no different. When an upstream supplier in a distribution system has limited capacity or inventory, downstream demand may exceed available supply. The supplier must then employ a *capacity allocation mechanism* to convert an infeasible set of demands into a feasible set of output assignments. Such a scheme inherently divides the downstream markets into winners and losers as it is possible to increase the allocation to one market only by shorting another. In an integrated system, the decision maker can dole out available output in order to maximize the system-wide return. Here we will focus on decentralized supply chains in which the supplier and the buyers are all independent firms seeking to maximize their own profits. In such a setting, the allocation mechanism does not exist in a vacuum and buyers may distort their orders or other actions in order to gain a more favorable allocation. The allocation scheme may consequently be seen as part of the supplier's marketing mix for influencing the behavior of its channel partners.

ALLOCATION MECHANISMS IN PRACTICE

Allocation schemes have wide application and considerable consequences. At one time or another, pharmaceuticals [1], computers [2], paper towels, and liquid detergent [3] have all been on allocation. Allocation of scarce capacity also plays a major role in the automotive industry, and a significant body of research has focused on this setting. There are several reasons for this. First, automakers are much bigger than their dealers. Where a packaged goods manufacturer might have to negotiate with powerful

retailers, automakers are able to dictate their terms. Second, several government bodies in the United States regulate dealings between automakers and their dealers, so automakers must explicitly formulate and announce their allocation schemes. Finally, because vehicles are expensive and have large profit margins, receiving more of a hot product makes a nontrivial difference in a dealership's profitability.

The case of Dave Smith Motors illustrates the impact allocation schemes can have. Located in Kellogg, Idaho, a town of less than 3000 people, the firm sold over 4000 Dodge pickups in 1996, more than any other dealer in the nation. Key to Dave Smith's ability to sell so many vehicles was Dodge's allocation system. Like most automakers in the US market, Dodge used a variant of *turn-and-earn*. Under this scheme, an initial allocation of vehicles is made and a dealership earns more product by turning (i.e., selling) units. In the case of Dave Smith Motors, its willingness to price aggressively—and Dodge's willingness to keep sending it more vehicles—allowed it to dominate its region [4]. Indeed, other dealers in the Pacific Northwest threatened to boycott Dodge unless the firm altered its allocation scheme to reign in Dave Smith Motors. The Federal Trade Commission ultimately intervened, siding with Dave Smith Motors [5].

As the example demonstrates, allocation schemes impact supply-chain performance. Several points are worth noting. First, turn-and-earn creates an incentive for dealers to "move the metal" and ramp up their sales rate [6]. This ability to direct product to where it is selling well is seen as one of the main virtues of turn-and-earn allocation. Toyota moved its Chinese dealership network to turn-and-earn allocation for this very reason. Toyota previously based its allocations on forecasts. When realized sales deviated from forecasts, there was little ability to redirect stock. Some dealers had excess inventory while others were turning away customers [7]. However, this

incentive to drive up sales is arguably a drawback of turn-and-earn since it may lead to high pressure tactics that increase sales today but risk long-term loyalty and brand value [8]. Further, turn-and-earn has been linked to commercial fraud. Dealers have falsified sales in order to win better allocations [9].

Turn-and-earn favors dealerships that somehow achieve scale and may create long-lasting asymmetries between dealers. A dealership cannot sell what it does not have, and it cannot receive more of a popular product unless it sells. Much like Dave Smith Motors, Woodhouse Ford of Blair, Nebraska, became a regional powerhouse by aggressively discounting full-sized pickup trucks. It is the third-largest Ford dealership in the nation, sells more F-series pickups than anyone else and outsells the next biggest dealership in the area by over 4000 vehicles a year. Again the automaker's reliance on turn-and-earn fueled the growth of a "super" dealer [10]. Beyond allowing some dealers to develop an entrenched lead, turn-and-earn can create regional biases in how firms allocate inventory. Toyota has traditionally been stronger on the West Coast of the United States than in the Midwest, making it hard for Midwestern dealers to get enough supply of popular models. Some Midwestern dealers have viewed national economic slowdowns as opportunities to expand their allocations [11].

Finally, it is worth noting that while allocation systems impact the actions of retailers and the evolution of markets, it is the supplier that gets to choose and control the allocation system. Dave Smith Motors is not merely a Dodge dealer. The firm owns franchises for a number of brands including GMC which like Dodge, counts on pickup trucks for much of its volume. Dave Smith Motors follows the same advertising and pricing practices for its GMC and Dodge dealerships. The GMC franchise has been successful but has not been as dominant (or troubling to other dealers) as the Dodge dealership. This has been in part because GMC has maintained tighter control over its allocation policies and not sent as much product to the dealer.

CAPACITY ALLOCATION AND THE BULLWHIP EFFECT

Academic interest in allocation schemes can be traced to the seminal work by Lee *et al.* [12] on the bullwhip effect. The bullwhip effect is the empirical supply-chain phenomenon in which the variance of order placed on upstream firms exceeds the variance of demand seen by downstream firms (see *Information Sharing in Supply Chains*). A potential cause of the bullwhip effect is shortage gaming. Consider a supplier selling to symmetric retailers. Each retailer is a monopolist in its market and faces a newsvendor problem. The supplier's total capacity is uncertain, and the retailers must order before knowing their individual demand realization or the total available capacity. The supplier sells at a fixed wholesale price and commits to allocating capacity in proportion to orders. If realized capacity is insufficient to meet all orders, retailers receive a fraction of the available capacity equal to the fraction of total orders they submitted. Thus, if a retailer's order represented one-fourth of all orders, he will receive one-fourth of realized capacity when capacity is tight.

The allocation mechanism forces the retailers into a game. They are monopolists in their markets but must compete for capacity. How a retailer should order depends on how every other retailer orders. Lee *et al.* [12] characterize the equilibrium of this game and show that the possibility of being placed on allocation induces the retailers to over-order, that is, to order more than they would if supply were certain to be ample and the sole concern were maximizing profits. The bullwhip effect thus appears. They also suggest a countermeasure to mitigate the bullwhip effect: allocate capacity based on past sales as with the auto industry's turn-and-earn system. Turn-and-earn allocation enforces a maximum allocation the retailer can receive and hence limits the ability to over-order.

This simple model and possible remedy has shaped the research agenda on capacity allocation mechanisms. Two streams of work have followed from it: one has focused on

one-period models and examined the properties of simple allocation mechanisms, while the other has looked at multiperiod models and the impact of turn-and-earn.

CAPACITY ALLOCATION IN A ONE-PERIOD MODEL

In examining single-period allocation models, we follow the formulation of Ref. 13. A single supplier sells to N buyers, usually thought of as retailers. The supplier has a fixed capacity K . We will consider having the supplier-set capacity at the end of this section. Like Lee *et al.* [12], we restrict the supplier to using a price-only contract with wholesale price w per unit. We will say something about alternative terms of trade in the final summary. Also, we ignore any scheduling costs or timing issues. For a discussion of capacity allocation in the context of scheduling problems, (see **Information Sharing in Supply Chains**). Finally, we assume that today's allocation depends only on today's orders and does not consider other factors such as customer satisfaction scores or the length of the retailer-supplier relationship although these may be relevant in practice.

Each retailer is a local monopolist. (We say something about competition later.) Retailer i 's revenue $R_i(y_i, \theta_i)$ depends on the amount of inventory (he stocks) and some market-specific parameter θ_i . The retailer may, for example, face a newsvendor problem and θ_i would be a parameter of the demand distribution. Only retailer i observes θ_i . $R_i(y_i, \theta_i)$ is concave in y_i and retailer i 's profit is maximized at $y_i^*(\theta_i)$. Let m_i denote the quantity retailer i orders from the supplier. $\Theta = \{\theta_1, \dots, \theta_N\}$ and $\mathbf{m} = \{m_1, \dots, m_N\}$. $F(\Theta)$ is the joint distribution of Θ , which is common knowledge. In contrast to Ref. 12, uncertainty about whether capacity will be adequate is driven by the retailers' needs and not uncertainty in the supplier's capacity.

The assumed sequence of events begins with the supplier announcing her allocations scheme $A(\mathbf{m}) = \{a_1(\mathbf{m}), \dots, a_N(\mathbf{m})\}$. Retailers then observe their respective pieces of market information and order. Next, the supplier allocates capacity according to $A(\mathbf{m})$,

receiving $wa_i(\mathbf{m})$ from retailer i . Retailer i then receives revenue $R_i(a_i(\mathbf{m}), \theta_i)$. Observe that the model implicitly prohibits transshipments between retailers.

$A(\mathbf{m})$ is a mapping from the set of orders to feasible allocations and must conform to three basic rules. First, if $\sum_{j=1}^N m_j \leq K$, $a_i(\mathbf{m}) = m_i$. Second, if $\sum_{j=1}^N m_j \geq K$, $\sum_{j=1}^N a_j(\mathbf{m}) = K$. Finally, $a_i(\mathbf{m}) \leq m_i$. The first assumption simply supposes that the allocation scheme is relevant only when capacity binds while the second assures that no capacity is wasted. The last assumption keeps the supplier from sending the retailer more than he requested.

A difference between the usual analysis of capacity allocation schemes and mechanism design models in the economics literature [14] deserves mention. The economics literature typically appeals to the revelation principle and concentrates on direct mechanisms in which agents truthfully report their private information. The question is then, what mechanism to use. The literature on allocation mechanisms generally fixes the mechanism and examines the behavior the scheme induces. In particular, the analysis studies whether it is ever the case that the retailer submits an order that exceeds his profit-maximizing quantity $y_i^*(\theta_i)$.

A frequently studied allocation function is *proportional allocation* [12,15]. Here $a_i(m_i) = \frac{m_i}{\sum_{j=1}^N m_j} K$. Under proportional allocation, each retailer loses the same fraction of his order. Alternatively, all retailers could have their order reduced by the same absolute amount. This leads to *linear allocation*. Ideally, all retailers would have their order reduced by $\sum_{j=1}^N m_j - K$. Obviously, a retailer with a very small order may be given a negative allocation. Linear allocation deals with this possibility by sequencing orders in decreasing size (i.e., $m_1 \geq \dots \geq m_N$) and fixing a value n' . We then have

$$a_i(\mathbf{m}, n') = \begin{cases} m_i - \frac{1}{n'} \left(\sum_{j=1}^{n'} m_j - K \right), & \text{if } i \leq n', \\ 0, & \text{if } i > n'. \end{cases}$$

n' is the largest integer less than or equal to N such that all retailers receive nonnegative allocations.

Both linear and proportional allocation are *individually responsive* [13]. If retailer i receives a nonnegative allocation when he submits m_i , he will receive a larger allocation if he submits $m'_i > m_i$ (assuming the other retailers' orders are unchanged). Many allocation rules share this property. In particular, Cachon and Lariviere [13] show that if the supplier knew each retailer's private information and wanted to allocate stock to maximize the sum of total profits, the resulting allocation rule would be individually responsive.

However, not all allocation rules are individually responsive. For example, consider *lexicographic allocation* or *uniform allocation*. Under lexicographic allocation, retailers are sequenced in a manner independent of their order size (say via a lottery) and retailer 1 receives $a_1(\mathbf{m}) = \min\{m_1, K\}$ and each subsequent retailer receives $a_i(\mathbf{m}) = \min\{m_i, K - \sum_{j=1}^{i-1} m_j, 0\}$. Uniform allocation begins like linear allocation by sequencing retailers such that $m_1 \geq \dots \geq m_N$ and fixing an integer $\tilde{n}$. Retailer i is then allocated

$$a_i(\mathbf{m}, \tilde{n}) = \begin{cases} \frac{1}{\tilde{n}} \left(K - \sum_{j=\tilde{n}+1}^N m_j \right), & \text{if } i \leq \tilde{n}, \\ m_i, & \text{if } i > \tilde{n}. \end{cases}$$

$\tilde{n}$ is the largest integer less than or equal to N such that $a_{\tilde{n}}(\mathbf{m}, \tilde{n}) \leq m_{\tilde{n}}$. Intuitively, uniform allocation first offers each retailer K/N units. If this exceeds some retailer's request, that retailer receives her full order and the excess capacity is split evenly among the other retailers.

Neither lexicographic nor uniform allocation spreads the pain equally. Under lexicographic allocation, at least one retailer will get as close as possible to his order while others may get nothing. Uniform allocation favors smaller markets. Small orders are filled completely while those placing larger orders all receive the same quantity.

We now turn to how retailers order, given an allocation mechanism. It is natural to

consider a Bayesian equilibrium in which (roughly speaking) each player seeks to maximize his payoff given his private information and his expectation of how others will play. Such an equilibrium may not necessarily exist. For an analysis of when an equilibrium exists, see Ref. 15. Suppose that an equilibrium exists, Cachon and Lariviere [13] show that it cannot be the case that all retailers truthfully report their optimal quantities $y_i^*(\theta_i)$ if the allocation mechanism is individually responsive. Further, any equilibrium under such a mechanism must involve some retailers inflating their orders.

Over-ordering and the bullwhip effect thus plague a large class of allocation mechanisms. In particular, if the supplier wanted to allocate inventory in order to maximize supply-chain profits, the retailers will inflate their orders and distort the allocation. That, of course, begs the question of whether there are any allocation mechanisms that result in the retailers truthfully submitting their optimal quantities. Clearly, the scheme cannot be individually responsive. A stronger condition delivers the desired sufficient condition. Let $(m'_i, m_{-i}) = \{m_1, \dots, m_{i-1}, m'_i, m_{i+1}, \dots, m_N\}$. Then suppose that for a given allocation mechanism $A(\mathbf{m})$ there does not exist an m'_i such that $a_i(m'_i, m_{-i}) > a_i(m_i, m_{-i})$ for all i and (m_i, m_{-i}) such that $a_i(m_i, m_{-i}) < m_i$. Then all retailers truthfully reporting their optimal stocking quantities (i.e., $m_i = y_i^*(\theta_i)$) is an equilibrium.

Both lexicographic and uniform allocation meet the stated requirements. Intuitively, if a retailer receives less than his full order under these schemes, no action can increase his order. (The assumption that the sequencing under lexicographic order is independent of the order size is essential. If orders were filled from, say, smallest to largest, this would not hold.) Under either lexicographic or uniform allocation, asking for more increases a retailer's allocation only if he is already receiving all of his order.

This result is in some sense robust. Cachon and Lariviere [13] show that under such a mechanism, truthful reporting is a dominant strategy. Retailer i will order $y_i^*(\theta_i)$ even if others deviate from the equilibrium. Further, it remains an equilibrium even

when all retailers know that capacity is certain to bind, a setting in which proportional or linear allocation would fail to deliver an equilibrium.

This is not to say that a blanket endorsement of either rule is in order. First, these schemes may not always induce truthful revelation when the setup of the model is tweaked slightly. For example, consider the basic issue of the bullwhip effect. Having distorted information is problematic when the upstream supplier plans on using that information. Here, information is simply being used to allocate current output. It is not being used for other decisions such as future capacity expansions. Obviously, if the retailers realize that today's orders will influence tomorrow's availability, they may well alter their orders.

Truthful revelation will also not necessarily withstand the introduction of competition for customers. Consider a market with two retailers engaged in quantity competition. The characteristics of the market are fixed and commonly known. Given that they bring quantities y_1 and y_2 to the market, the retail price will be $P(y_1, y_2) = \theta - (y_1 + y_2)$. If capacity were certain to be available and the retailers order simultaneously, they would each order the standard Cournot quantity $y_C = (\theta - w)/3$, where w is again the supplier's wholesale price. Now, suppose that capacity is less than $\theta - w$ and that the supplier commits to using lexicographic allocation where the ordering will be determined randomly after orders are submitted. For simplicity, assume that the retailers cannot withhold stock from the market (i.e., y_i must equal to $a_i(\mathbf{m})$). Having $m_i = y_C$ is not necessarily an equilibrium. Specifically, suppose that $m_1 = K$ but that $m_2 < K$. If retailer 2 is sequenced second by the supplier, he receives nothing and earns zero profit. If he is sequenced first, he will receive m_2 but the prevailing price will be $\theta - K$ since retailer 1 is certain to take all the remaining capacity. Given that the retail price exceeds w and is fixed given $m_1 = K$, retailer 2's best response is to also order K . Given competition, lexicographic allocation results in extreme order inflation and a *de facto* monopoly in the retail

market. For more on allocation with competition, see Refs 16–18.

A second consideration is that a one-period model is in some ways inadequate for the questions being asked. For example, in a one-period setting, how can order inflation hurt the supplier? It is well known that a supply chain operating under a simple wholesale price contract suffers from double marginalization (see **Supply Chain Coordination**). Because the supplier (presumably) sells above his or her marginal cost of production, each retailer's optimal sales quantity is too low from a supply-chain perspective. Competition in the retail market is one way of addressing the resulting inefficiency. Alternatively, an individually responsive allocation mechanism introduces competition for capacity, inducing each retailer to order more and (in some states of the world) sell more than they would if a nonindividually responsive scheme were used.

Further, higher orders imply higher sales for the supplier, increasing her profit. The supplier's gain must come at the expense of the retailers. The overall outcome for the supply chain is unclear. In a numerical study, Cachon and Lariviere [13] show that supply-chain profits generally improve when the allocation method is switched from uniform to linear if capacity is fixed. It is even possible that average retailer profits improve with the move. For intuition on why supply-chain profit increases, note that the derivative of a retailer's profit function at $y_i^*(\theta_i)$ is zero. Hence, increasing the order size is initially costless to the retailer but strictly beneficial to the supplier. To understand how the retailers may benefit from being forced to compete more aggressively for stock, observe that uniform allocation leaves open the possibility of profitable trades between the retailers. A retailer in a small market receives his full order and values the last unit at zero while a retailer in a large market is shorted and would pay a premium over the wholesale price for another unit. Linear allocation reduces the extremes of these marginal valuations. Retailers in smaller markets will see their profits fall but the gains captured by

those in large markets may swamp the small market losses.

Allowing the supplier to choose his or her capacity adds a wrinkle. If the supplier uses a truth-inducing mechanism such as uniform allocation and has a constant marginal cost of capacity c , she faces a newsvendor problem (see **News vendor Models**). Let $\Psi_U(x)$ denote the distribution of total orders the supplier receives when she uses uniform allocation. $\Psi_U(x)$ does not depend on K . Consequently, the optimal capacity for uniform allocation K_U solves $\Psi_U(K_U) = \frac{w-c}{w}$. The distribution of total orders under linear allocation $\Psi_L(x|K)$ does depend on available capacity. Cachon and Lariviere [13] shows that each retailer orders less as capacity increases, implying that $\Psi_L(x|K_0) \leq \Psi_L(x|K_1)$ for $K_0 \leq K_1$. They further show that for the optimal capacity under linear allocation K_L , it must be that $\Psi_L(K_L|K_L) \leq \frac{w-c}{w}$. Thus, when retailers are ordering strategically, it will seem as if the supplier undershoots the relevant newsvendor fractile. However, if she were to expand capacity, demand would collapse.

These results do not guarantee an ordering of K_U and K_L . Numerically, one can show that moving from uniform to linear allocation can result in either an increase or a decrease in capacity. An increase in capacity is likely when the cost of capacity is high relative to the wholesale price. Under uniform allocation, such settings result in very low capacity. Moving to linear allocation allows the supplier to expand capacity while still generating enough competition so that system capacity is nearly fully utilized. This is yet another way that an allocation mechanism that induces over-ordering can improve supply-chain profit: more aggressive ordering may result in more capacity being built.

TURN-AND-EARN: BASING ALLOCATION ON SALES HISTORIES

We now examine the implications of tying current capacity allocation to prior sales as exemplified by the auto industry's practice of turn-and-earn. Any model of such a system must have at least two sales periods. Also, there must be some variation in demand so

that capacity is not binding (assuming that retailers order myopically) in some states but is binding in others. Low demand states allow one to study how the possibility of being put on allocation in the future induces retailers to alter their current sales policies in order to capture a larger share of the capacity in the future.

This is the basic structure assumed in Ref. 19. The model has two retailers who are both local monopolists. Each market is characterized by a linear demand curve. Given a sales quantity y , the retail price will be $P(y) = \theta - y$, and a retailer's current profit is maximized by selling $y(\theta) = \frac{\theta-w}{2}$. The intercept θ can vary by period and takes one of two values. In the high demand state $\theta = 1$ and in the low demand state $\theta = \alpha < 1$. The markets are perfectly, positively correlated: when demand is strong in one market, it is strong in the other.

The supplier has a fixed capacity K and $\alpha - w < K < 1 - w$. When demand is low, there is enough capacity for both retailers to receive their profit-maximizing quantities. When demand is high, the supply chain will be capacity constrained. There are two periods, and the wholesale price is fixed over the horizon. For simplicity, ignore discounting and suppose first-period demand is low ($\theta = \alpha$) while second-period demand is certain to be high ($\theta = 1$). (It is straightforward to allow second-period demand uncertainty.) Further assume that the retailers cannot carry inventory from one period to the other. We will explain how carrying inventory changes the model momentarily.

Two allocation methods are considered, fixed allocation and turn-and-earn. Under fixed allocation, each retailer has a "guaranteed allocation" of half of available capacity (i.e., he or she is certain to receive $K/2$ if he orders at least $K/2$). He may also claim any capacity that the other retailer does not want. Hence, given orders m_i and m_j , retailer i is allocated $a_i(m_i, m_j) = \min\{m_i, K/2 + [K/2 - m_j]^+\}$, where $x^+ = \max\{x, 0\}$. Fixed allocation is arguably a mere straw man, but it is simple, stationary, and guarantees symmetric treatment of the symmetric retailers. It thus forms a useful base case.

Analysis of the retailers' actions is straightforward. Fixed allocation functions much like uniform allocation in the single-period setting and thus, there is no reason for a retailer to distort his order. Each retailer orders $y(\alpha)$ in the first period and $y(1)$ in the second. Given our assumptions on capacity, each receives $y(\alpha)$ in the first period but gets only $K/2$ in the second.

Turn-and-earn is more involved. First-period allocations are the same as under fixed allocation, but second-period allocations depend on first-period sales. Let q_i denote retailer i 's first-period sales quantity and suppose $q_i \geq q_j$. Retailer i is then designated as the leader and will receive a favorable allocation in the second period. Specifically, his guaranteed allocation rises from $K/2$ to $K/2 + q_i - q_j$ and given orders, he receives

$$a_i(m_i, m_j) = \min\{m_i, K/2 + q_i - q_j + [K/2 + q_j - q_i - m_j]^+\}.$$

Retailer i 's gain must come at the expense of retailer j . As the follower, his guaranteed allocation is $K/2 + q_j - q_i$ and

$$a_j(m_j, m_i) = \min\{m_j, K/2 + q_j - q_i + [K/2 + q_i - q_j - m_i]^+\}.$$

As the players move into the high demand second period, there are distinct advantages to being the leader. Capacity is certain to bind and at least the follower (if not both players) will have allocations below $y(1)$. Additional supply would then have a positive marginal valuation. This leads to a distortion in first-period sales. If retailer j anticipates being stuck as the follower in the second period, increasing his first-period sales above $y(\alpha)$ has zero initial marginal cost but has a positive marginal benefit (holding retailer i 's sales quantity fixed).

Cachon and Lariviere [19] show that the retailers do, indeed, increase their first-period sales. The supplier then certainly benefits from turn-and-earn. His or her first-period sales increase relative to fixed allocation and the capacity remains fully utilized in the second period. The news for the retailers is less optimistic. They effectively

play to a draw. The unique equilibrium has them selling the same quantity in the first period. Increasing sales is more a defensive necessity than a means to a second-period advantage. The impact on supply-chain profit is consequently unclear.

Moving from fixed allocation to turn-and-earn also has an ambiguous impact on the supplier's choices when the supplier is free to set capacity and wholesale price. Suppose that demand in the second period is not certain to be high but will be high with probability ϕ . The supplier under fixed allocation will choose either $K = 2y(\alpha)$ or $K = 2y(1)$. Turn-and-earn admits a third possibility $k(w)$ such that $2y(\alpha) < k(w) < 2y(1)$. $k(w)$ is the largest capacity that will be fully utilized in the first period under turn-and-earn. This raises the possibility that the supplier brings more capacity to the market under turn-and-earn. He or she may also lower the wholesale price. Either of these changes may produce a sufficiently large benefit for the retailers so that they prefer competing under turn-and-earn to operating under fixed allocation.

Given that supply may be tight in the second period, having the retailers carry inventory between periods would be desirable. When this is added to the model, the retailers continue to increase their first-period sales rate under turn-and-earn. They may also distort the inventory decision. When capacity is very tight, the retailers reduce their inventory in order to bolster their first-period sales. This is clearly bad for the supply chain; the supplier's sales remain fixed (because capacity binds in both periods) and the retailers are selling more at a low price in the first period instead of saving inventory for the larger, more profitable second-period market.

In extending this model, it is straightforward to see that if there is another action that will increase sales, the retailers will increase this effort as well. For example, the retailers might face newsvendor problems instead of deterministic demand curves. If they could stochastically increase the demand distributions they face via advertising, they would advertise more under turn-and-earn than under fixed allocation. Similarly, if the retailers sold substitute products such as new and used cars, they would sacrifice sales of an

unconstrained product (used cars) to boost sales of a capacity-constrained product (new cars). This clearly benefits the supplier. However, suppose that the supplier provides both products (say, two car models in the same product line). Now if allocation of the hot-selling, capacity-constrained model depends only on its sales, the retailers have an incentive to reduce sales of the other product, which may harm the supplier. Here, the supplier would benefit from tying the allocation of a hot product to the total sales of the product line. See Ref. 20 for more on this logic.

The basic model of Ref. 19 captures the incentive to move the metal inherent in turn-and-earn but leaves a number of important issues unexamined. The symmetric, deterministic nature of the model keeps one retailer from gaining an advantage in equilibrium. Even if it were possible to gain an advantage, its limited two-period horizon does not allow one to examine the extent to which a leading retailer would fight to maintain his allocation. Finally, interest in turn-and-earn followed from research on the bullwhip effect but nothing in the model allows one to examine whether this allocation scheme helps reduce the bullwhip effect.

Lu and Lariviere [21] tackle a number of these issues. They consider an infinite horizon model in which the retailers face linear demand curves. The demand intercepts now have two components. The first is similar to the original [19] and is correlated across markets. This again reflects common market conditions but can now take three values. Under fixed allocation, capacity would bind only in the highest demand state. The common market condition evolves according to a Markov process. The second intercept term is a local shock that is drawn independently for each market. The shock for market i is only observed by retailer i . These modifications to the model allow for a richer story. Three common demand states imply that turn-and-earn induce higher sales in some states with excess capacity but not necessarily in all such states. The local shocks create the possibility that one retailer might gain an advantage. Further, the privately observed noise allows

one to evaluate the impact of turn-and-earn on the variance of demand placed on the supplier.

The analysis begins by finding a Markov perfect equilibrium between the retailers. As one would expect, the retailers still increase their sales relative to fixed allocation. More interesting is what happens when one retailer gains an advantage. The leader is willing to incur some cost (through selling more in less favorable markets) in order to maintain his lead. How long leadership persists depends on capacity tightness and demand volatility. Limited capacity makes leadership more valuable. Limited demand volatility keeps the leader from having to face the lowest demand state. Once the market enters the lowest demand state, the leader gives up trying to maintain his position. Stated another way, a recession re-levels the playing field. Finally, Lu and Lariviere [21] show that turn-and-earn can mitigate the bullwhip effect. By creating an incentive to boost sales, turn-and-earn induces the retailers to absorb unfavorable demand shocks as opposed to passing them on to the supplier. Thus turn-and-earn not only divorces allocation from possibly inflated orders, it actively counters the bullwhip effect.

SUMMARY

The choice of a capacity allocation mechanism is an effective—and to some extent underappreciated—means for a supplier to influence the behavior of downstream supply-chain partners. It influences both, how downstream buyers order and how they act. A well-designed allocation scheme has the potential to increase the supplier's profit as well as total supply-chain performance. The buyers may also benefit, especially when the allocation scheme induces the supplier to provide more capacity.

There are a number of open research issues in capacity allocation. One is the impact of alternative terms of trade. Essentially, all work on allocation schemes assumes that transactions are governed by wholesale price-only contracts. Consequently, given a total amount of orders,

the supplier's profit is fixed. This would not be the case under, say, a returns policy if retailers faced stochastic demand that varied across markets. If the supplier were responsible for unsold stock, she would have a greater interest in efficiently allocating capacity.

Another open issue is how to deal with asymmetric retailers. Some existing models allow retailers to be privately differentiated ex-post. The supplier cannot take advantage of this information upfront in designing the allocation scheme. In reality, a supplier knows which retailer has a favorable location in a large city and which is barely getting by in a rural town or which is a large chain representing a significant part of the supplier's sales and which is a mom-and-pop operation. A well-conceived allocation scheme should be able to take advantage of this knowledge. How this can be done for the benefit of the supplier or the supply chain while conforming to relevant antitrust laws has not been studied.

Finally, existing work has assumed a monopolist supplier. This is sensible to the extent that, say, a car dealer has only one source for a hot model. However, products exist in competitive markets and retailers have a choice over which products to stock or for which to exert promotional effort. How allocation schemes impact these decisions is an open question.

CAPACITY PLANNING IN HEALTH CARE

JONATHAN PATRICK
PEDRAM NOGHANI
University of Ottawa, Ottawa,
ON, Canada

At one level, one could argue that capacity planning has been made relatively simple by long-standing equations developed in the queuing theory literature. Given a performance metric of the form, $x\%$ of patients need to be seen within y units of time, queuing theory can easily determine the necessary capacity to make this a reality. In truth, if even these simple formulations were used more frequently in health organizations, we would not see the kind of demand/supply mismatches that are so common and lead to such incredibly long wait times. An excellent example of the benefit of these simple queuing methodologies can be found in the research of Green [1, 2].

The importance of the form of the performance metric, though well known in the literature [3], often goes unrecognized by healthcare managers. Clearly without a performance metric there is no required capacity while as soon as one is imposed (most helpfully in the form given above) then implicitly a capacity requirement has been imposed as well. Back of the envelope rough estimations using queuing theory are helpful but obviously a lot more can be said about the additional challenges that complicate most capacity planning problems in health care. The ones we will touch on briefly in this article are patient behavior, the presence of multiple patient classes, and the strong possibility of downstream blocking. These are by no means an exhaustive list but they are perhaps three of the more common and significant challenges. We will first discuss the impact of these additional challenges and then circle back to discuss the attempts to address them and the challenges that yet

remain. This article can hardly hope to provide an exhaustive look at the literature but hopefully will provide some lay of the land as well as some hints as to potential solutions and future directions.

CHALLENGES TO CAPACITY PLANNING IN HEALTH CARE

Patients are not widgets. This quite obvious statement has a number of implications for capacity planning in health care. It means that one can assume that each patient coming through the door is going to have some unique features in terms of the type of resources required to treat them as well as the urgency with which they need to access those resources. Moreover, the non-widget like nature of patients means that they will not necessarily behave as one would like or imagine.

Patient Behavior

Outpatient clinics, for instance, are constantly dealing with idle capacity created by patients failing to show for an appointment. This has led to a prolific stream of literature on optimal overbooking policies as well as a strong push for what is called *open access* or *advanced access* scheduling. However, while this is the most commonly researched impact of patient behavior, other impacts are also present. Most research, for instance, assumes that patients will accept the appointment offered to them. In reality, wait times are often artificially increased by patients who refuse to take the first appointment offered to them either because it does not fit their own schedule or because they choose to wait for their preferred provider. These user-side delays are rarely recorded in the data sets leading to an inflated sense of the actual wait times for a given health service (though how inflated is a matter of contention) and posing a significant challenge in terms of planning capacity.

Presence of Multiple Patient Classes

Many health needs are not planned months in advance where one has the leisure of smoothing out demand through intelligent advanced scheduling. Health needs are often sudden and urgent leading to many health services having a significant proportion of demand that must be served close to, or even on the day of, the original request. Such a reality greatly hampers the ability of a health service to manage the available capacity intelligently.

The individuality of patients also becomes a significant challenging factor as patients arrive to a health service not only with varying levels of urgency but also with varying conditions that require differing amounts of resource consumption as well as potentially different types of resources. For example, many hospitals have close to 1000 different surgical types each with their own separate distribution for length of surgery as well as length of recovery time and some of which require specialized equipment. How much capacity is needed in such a situation is clearly dependent on how these patients are scheduled. Poor scheduling, for instance, could lead to peaks and valleys in the distribution of occupancy rates in the wards leading to a higher capacity requirement. A more intelligent scheduling policy could meet the same performance target with significantly less capacity. In addition, the larger the urgent class and the shorter the window within which to book them, the less flexibility one has in scheduling and thus, again, the greater the required capacity in order to meet the same performance target.

Downstream Blocking

A third complicating factor is that patient care rarely involves a single service. More frequently, patients move through a series of services and not necessarily in a serial manner as they may loop back to revisit a previous service due to a complication. Thus, for instance, a patient may enter the emergency department of a hospital, be transferred to a ward bed for a period of time and then require time in a rehabilitation facility before finally ending up in a long-term care home. From the

long-term care home, they may relapse and require a second visit to the hospital. What happens all too frequently is that a patient gets stalled in this journey due to a lack of capacity at the next stage in their care. In much of the developed world, there is a significant back log of patients who remain in the hospital after the acute phase of treatment is finished simply because there is no capacity at the community care facility (i.e., long-term care home) at the next stage in their care pathway. These patients, therefore, block acute care (AC) beds delaying patients in the emergency department who are awaiting admittance to the wards. Treating a single facility in isolation (as the simple queuing equations mentioned at the outset would do) is therefore often insufficient as the impact of downstream blocking may mean a significant increase in the required capacity to meet the specified performance target.

Surge Capacity

Finally, it is crucial to remember that it is people being serviced and that failure to receive service in a timely manner can have dire consequences to their well-being. Thus, one cannot simply write-off the tail of the wait-time distribution. The common practice used in other settings of refusing service in order to deal with surges in demand is often not an option for a health service. This leads to the absolute necessity for health services to invest in surge capacity—capacity that an organization can turn to in periods of high demand. Surge capacity can take on a number of forms but the two most common are overtime and transfers to another facility. These typically come with a higher service cost but can often be more cost-effective than continually carrying the additional capacity required to meet the peaks in demand.

What the above discussion hopefully demonstrates is twofold. First, health care capacity planning is often complicated by additional factors that make the simple capacity requirement calculations less effective than in other settings. Second, the required capacity is determined not only by the performance target that has been put in place but also by how the complicating

factors are dealt with both through investment in surge capacity and the choice of scheduling policy. Thus, any discussion on capacity planning needs to make mention of how that capacity is managed. The primary manner by which capacity is managed is through the schedule.

The health care scheduling literature can roughly be divided into *advanced scheduling* and *appointment scheduling*. Advanced scheduling refers to the policy that determines how far in advance to book each request for service. It is through advanced scheduling that the daily fluctuations in demand are smoothed out—an advantage that can play a significant role in reducing the capacity required to meet a given performance target. Appointment scheduling refers to the policy that determines the order and the start times of each patient booked into a given day. It is through the appointment schedule that the wait times on the day of service, the idle time, and the use of overtime are controlled.

ADDRESSING THE CHALLENGES

Patient Behavior

Patient choice is a challenging area of research because (i) it is unpredictable by nature and (ii) very few health services collect the data that would allow you to model it. For instance, few health services collect information on what booking appointments were refused by a patient and for what reason. Gupta and Wang [4,5] developed multiple Markov decision process (MDP) models that mimic patient choice both in terms of provider preference (loyalty to their own physician in a multi-physician clinic) and in terms of time of day preference. They examine a single day's booking from a revenue management perspective with the decision variables being whether to accept or reject an incoming request for service. They were able to partially describe the form of the optimal policy but implementation remains a challenge as the policy depends on data that is rarely collected. Feldman *et al.* [6] provide some evidence for the time of day preference of patients based on a

discrete choice experiment conducted at a large health center. They build a model for appointment scheduling that incorporates these choice decisions where the decision of the provider is which appointment slots to offer to each arriving demand. They incorporate both cancellations and no-shows and demonstrate the superiority of a dynamic system over a static one. In other words, they demonstrate improved performance associated with taking into account the state of the system (i.e., current bookings) and patient behavior in determining the booking policy.

Data on patient no-shows are more commonly collected with studies that have linked no-shows to the length of the lead time (time between request and service), the postal code of the patient, and the weather to name just three [7]. An impressive amount of research has led to a number of policies based on different formulations of the problem all telling a very similar and somewhat predictable story—no-shows can be mitigated by overbooking but how that overbooking is best implemented is an open question [8–11]. Dome-shaped policies that book clients closer together early and late in the day are generally accepted to work well provided that service times come from the same distribution for all patients [12,13]. Double booking early in the day has also demonstrated fairly good performance as has the Bailey–Welch rule that schedules a number of patients right at the beginning of the day and then separates further appointments by the average service time [14]. Of course, which policy is deemed optimal depends in large part on the relative importance one places on the relevant performance metrics. Most papers in this vein use some combination of patient wait time, server idle time, and overtime. The actual weightings play a significant part in terms of the shape of the optimal policy. For instance, increased weight on the wait time of patients will clearly be detrimental to the Bailey–Welch rule, whereas if overtime and idle time are the primary concerns then the Bailey–Welch rule may do fairly well. It is worth noting that, in most cases, the capacity is deemed to be fixed when determining the optimal appointment schedule, whereas

it is quite likely that the optimal appointment schedule may in fact be a function of both the available regular-hour capacity and the surge capacity options. This is certainly an avenue for future research. Also lacking at present is a model that determines both the order and the start times of a set of patients booked on a given day. Most appointment scheduling models either assume the order is known [15] or else assume patients are of one type (thus negating the importance of the order). One heuristic that appears to perform well is to book patients starting with the one with the least variable service time and working down to the one with the most variable service time. However, this has the detrimental side-effect of leaving the more complex patients to later in the day.

The detrimental impact of no-shows combined with patient dissatisfaction with over-booking has led some researchers to advocate for a form of scheduling called *open access* that essentially books patients on the day the request is placed [16]. The rationale is that no-shows are much less likely if the lead time is zero and moreover same day access is generally seen as an important benefit for the patient. However, it is clear that advanced scheduling provides significant advantages in terms of both the amount of regular-hour capacity required and the amount of surge capacity utilized. Even a small booking window of one day [17] or a few days [18] has been shown to significantly improve the efficiency of a clinic compared to “open access.” Models that determine the optimal (potentially dynamic) booking window that would allow a health service to take advantage of advanced scheduling without unnecessarily inflating wait times would certainly add value to the literature.

Presence of Multiple Patient Classes

Less widely studied has been the impact of multiple patient classes. This is unfortunate as the impact of multiple patient classes is perhaps of much greater import than the impact of “no-shows” while at the same time not suffering from the lack of data that compromises much of the research on patient behavior. Patient classes are generally the

result of differences in urgency and/or differences in resource consumption. The general challenge is how to manage capacity in such a way that each class receives service in a timely manner and such that the available capacity is used efficiently. Gerchak and Gupta [19] looked at this problem in the context of elective and emergency surgeries with the decision simply being the number of elective surgeries to book on a given day. They demonstrated that the optimal policy is not simply a cut-off policy that reserves a fixed number of slots for emergency surgeries but rather that the number of elective surgeries to book depends on the length of the elective wait list. However, they do not provide an actual schedule for the elective surgeries. Models that seek to book patients from multiple classes in advance quickly run into tractability issues. Thus, work has focused on approximation techniques [20, 21]. One of the take home messages from this line of research is that the driving force behind the amount of capacity required is the size of the highest priority class and even more importantly the length of the window within which they have to be booked. In other words, flexibility in the booking of the highest priority class is the best means of reducing capacity requirements [22]. Second, intelligent use of short bursts of surge capacity can greatly reduce the necessary capacity and significantly reduce the cost of meeting a given performance target [21]. As mentioned earlier, one cannot simply ignore the tail of the wait-time distribution and thus fixed wait-time targets are often assigned instead of the probabilistic rule mentioned at the outset. However, rather than seeking to build sufficient regular hour capacity to meet the target, it is often much more beneficial to address the tail through surge capacity. More recent work, based on more sophisticated approximation techniques, has demonstrated significant improvements in capacity utilization (in terms of reduced idle time and surge capacity utilization) over previous attempts yielding policies that will on occasion book patients late (if the downstream congestion is minimal) or will act more pro-actively to initiate surge capacity in states where anticipated congestion is significant [23].

One significant area of potential research involves the intelligent merger of the appointment scheduling and advanced scheduling problems. Currently, these problems are treated as independent problems by solving advanced scheduling problems as though service times were deterministic (thereby avoiding the impact of the appointment schedule) or else by solving appointment scheduling problems as though the number of patients to be scheduled was an exogenous variable outside of the control of the manager. Ideally, these two scheduling problems would be solved together as the performance of the one is clearly dependent on the form of the other.

Downstream Blocking

More challenging still are those settings where appropriate capacity planning requires the simultaneous consideration of multiple resources and where each patient's flow through the various services is far from straightforward. Two excellent examples of this challenge are surgical capacity planning (where patients require both time in the operating room (OR) and recovery time in the wards) and patient flow through acute care (AC) and into community care (where patients need access to certain community services before they can be discharged from AC). Tackling the first has led to a number of models that attempt to minimize the peak load in the ward based on restrictions on the performance of the ORs—usually in the form of ensuring that a certain throughput is maintained or a given threshold utilization is achieved [24–26]. Seeking to optimize capacity in the ORs and the wards simultaneously becomes a multi-objective problem where the desire is to meet at least three competing performance targets—wait-time thresholds for patients, efficient use of OR time, and efficient use of ward capacity. In this setting, being significantly under capacity is often viewed as just as much an issue as being over capacity. One attempt to solve the combined problem can be found in Astaraky and Patrick [27] who develop an MDP model that seeks to minimize precisely this three-pronged objective. Tractability issues force them to apply

approximation methods that are nonetheless able to demonstrate significant improvement in wait-time management without significant increases in overtime in the OR or congestion in the wards. Key to their results is the grouping of patients within a surgical specialty through clustering techniques so that within each group service time distributions (both OR time and recovery time) are reasonably tight and well-defined. Implementation would involve wresting away some of the control of the scheduling process that currently resides with the surgeon. With only the block schedule (which surgeon receives OR time on what day) under the control of most hospitals, capacity planning that adequately addresses both OR capacity and ward capacity is severely hampered.

The progression of patients out of AC and into community care has not received nearly enough attention in the operations research literature considering the considerable shift in emphasis within health services away from the hospital and toward the community. Day surgery has vastly increased followed by extensive rehabilitation services provided in the community. The increasing number of elderly patients who require 24-h (non-acute) care has led to significant increases in the need for long term care facilities and supportive housing. The lack of appropriate capacity plans for these facilities has led to significant backlogs in hospitals as patients whose AC treatment is finished block acute beds for want of the appropriate services in the community [28].

The importance of this issue in health care was highlighted at least 25 years ago with the work of Weiss and McClain [29]. They developed a queuing system with state-dependent service rates in order to model discharges from the hospital that require community service. Weiss and McClain predict the probability distribution of the number of clients waiting in the hospital for transfer to a community service. Their model, however, does not provide a means of predicting the impact of downstream blocking.

There is, however, a stream of literature that has progressively improved the ability of queuing network models to predict the

impact of downstream blocking. This literature can be described as a series of progressively improved heuristics for estimating the probability of blocking given a capacity plan for a network of services. All of the heuristics provide a means of estimating the blocking probability and the estimated size of the wait list at each node. The improvements in the heuristics are twofold: better accuracy in small networks where the optimal solution can be computed and a reduction in the limiting assumptions that allow for the application to a wider variety of scenarios. The first of these heuristics was developed by Takahashi *et al.* [30] using an open queuing network system with feed-forward flows and finite buffers between stations. They introduce an approximation method for open restricted queuing networks in which the service time and arrivals have exponential and Poisson distributions, respectively. The approximation method is capable of providing various performance measures such as blocking probabilities and output rates of general open restricted queuing networks.

In a more recent health applications study, Koizumi *et al.* [31] use a queuing network system with blocking to analyze congestion in a mental health system in Philadelphia. They use a multi-server model to present both mathematical and simulation results. Their system consists of three types of psychiatric institutions. Patients enter the network from either an acute hospital or the community and proceed through the network in a sequential manner (no feedback loops). They use the same approximation methodology that Takahashi *et al.* developed but extended to a multi-server model. Two performance indicators are used in their model: number of patients waiting to enter each facility of the system and the associated waiting time in steady state.

Finally, a recent study by Brettahauer *et al.* [32] presents a new heuristic method for queuing networks with blocking. They use a queuing network system to model patient flow between intensive care (ICU), step-down (SD), AC, and post-acute care units (PAC). Of note is that the heuristic can be applied to scenarios where patient flow involves feedback loops or where patients may enter

the system at any node in the network. The aim of their study is to find the best mix of beds across the hospital's inpatient units in order to provide the highest quality of care possible given a limited budget. Since the approximation of the blocking probabilities is determined algorithmically, there is a significant challenge presented in utilizing these heuristics to determine the optimal capacity at each node (as there is no closed form solution for the blocking probability). Brettahauer *et al.* resort to enumeration to find the optimal bed allocation (in order to minimize a weighted sum of the probability of blocking at each node) between the services given a fixed budget. A method for optimally determining capacity that nonetheless makes use of the performance metrics outlined in algorithms such as Brettahauer *et al.*'s would certainly add to the literature.

What all three heuristics demonstrate is the significant impact of downstream blocking. Healthcare managers have time and again neglected downstream blocking effects, choosing to focus on the high impact or critical resources (such as an emergency department) often at the expense of health resources that are of less immediate consequence (such as long term care). Such short-sighted planning has led to significant issues in precisely those high impact regions of the health system—not because they are under-capacitated but simply because of the inability to off-load patients in a timely manner to underfunded, under-resourced downstream facilities.

INSIGHTS FOR HEALTHCARE MANAGERS

It is understandable, given the complexity of managing capacity in a health care setting, that managers have often felt overwhelmed and have been limited to reacting to crisis rather than anticipating it. What managers need to be aware of is that there are viable models that can help determine and minimize capacity requirements through intelligent scheduling—even in complex situations where multiple patient classes are involved with potential no-shows and with multiple resources consumed in sequence.

Some of these models do require sophisticated software for implementation but others have developed simple heuristic policies that could be easily implemented. Managers also need to realize that limited use of overtime is not a negative and may in fact be the most cost-effective means of meeting a given performance target. Certainly some form of surge capacity is an essential component of an efficiently run health service.

For the operations researcher, there is a wealth of potential in this field for future avenues of research many of which have been mentioned above. One key message is that we need to stop looking at part of the health system in isolation but rather to recognize the inter-connectedness between the various parts and the impact that inter-connectedness has on how we plan and manage capacity. We also need to provide a more reflective assessment of health care capacity planning that looks at long term trends and does not necessarily focus on the current point of crisis that may in fact be merely a symptom of a much larger problem.

CONCLUSION

The individuality of patients with each having unique health service needs has led many health managers to believe that quantitative models simply cannot be of much use. This is, in my mind, an over-reaction to what is a legitimate concern. Operations researchers working in the field of healthcare management need to recognize this individuality and the significant complexity it adds to scheduling and capacity planning. It ought to instill in us a certain amount of humility and cautiousness in presenting the results of our models, recognizing the difficulty of accurately representing how people behave and the necessarily simplified representation of reality upon which our model depends. Einstein once wrote that “as far as the propositions of mathematics refer to reality, they are not certain and as far as they are certain they do not refer to reality.” As operations researchers, we are always seeking to find that balance between making the model complex enough to be useful and yet simple enough to be tractable. This unavoidable

trade-off is certainly evident in the numerous attempts to plan capacity in the health care setting. Approximation techniques are one means of increasing complexity without losing tractability though of course at the loss of optimality! Unfortunately, that loss of optimality may be necessary if our models are to contain the amount of complexity required in order to be of any use to healthcare managers.

CAPACITY PLANNING

SAMPATH RAJAGOPALAN
Marshall School of Business,
University of Southern
California, Los Angeles,
California

Capacity planning and expansion is an important activity for a firm for several reasons. First, capacity levels determine how much output a firm can produce which in turn determines the level of demand that can be satisfied. Also, capacity levels impact how quickly a firm can respond to customer requests or supply chain disruptions. Thus, capacity levels impact sales volume, revenues, and profits both in the short and long run. Second, capacity decisions involve significant capital commitments that are either partially or fully irreversible. For instance, once an oil company has built a refinery, it cannot easily change its decision and recover its costs fully. Third, capacity expansion decisions in many industries involve significant scale economies and therefore are made infrequently. So, they are based on long term demand forecasts which tend to be uncertain. For instance, capacity decisions in the power sector are based upon demand forecasts 20 years into the future [1]. Together with the irreversibility of these decisions, this implies that making a sound capacity decision is critical for a firm's operations. In this article, we discuss the main elements and trade-offs in capacity decisions and some typical models used in capacity planning.

MAIN ELEMENTS OF CAPACITY DECISIONS

The main elements of a capacity decision involve issues related to size, timing, type, and location of the capacity addition, and we discuss these in some detail next. Also, a facility often contains multiple resources and in some industries, capacity levels may

depend on the level of all these resources. For instance, at an airline, capacity is a function of the type and number of planes, number of gates at the airports it operates, pilots, flight crew, ground crew, and so on. So, careful consideration needs to be paid to all these factors. It should be kept in mind that several elements of capacity decisions are often intertwined but we discuss some of them separately for clarity in exposition.

Capacity can be defined as the *maximum output of a system or resource per unit time*. While this may appear to be precise, there are several measurement issues in practice. A steel plant's capacity may be defined as 500,000 tons per year but this may be a *theoretical* or *design* capacity (also referred to as *rated* or *engineering* capacity) that can be achieved only under ideal conditions. The *effective* capacity may be lower, say because the plant requires downtime for scheduled maintenance. The *actual* capacity may be even lower due to yields, defects, equipment breakdowns, and so on.

Size and Timing

Firms add to existing capacity in response to (unexpected) past demand growth and in anticipation of future demand growth. When a firm builds a plant of a certain capacity to meet this demand growth, the added capacity may be fully utilized after some years and it may have to add capacity again. Thus, the size of the current capacity addition impacts the time at which the next capacity addition is made and so the size and timing decisions are inextricably linked. For example, Genentech [2] found that demand for its drugs was growing fast and it had to make several capacity expansion decisions during the past decade and a half. The size of each expansion has impacted the timing of future expansions. One of the main benefits of a large expansion is economies of scale, that is, average cost per unit of capacity decreases as the expansion size increases. For instance, the capacity cost in heavy process industries such as chemicals and petroleum exhibit

substantial scale economies [3,4]. Scale economies arise due to the presence of fixed costs that do not vary with the volume of expansion or marginal costs that decline with volume. So, the capacity cost function is often represented as a concave increasing function of volume to depict the decreasing average unit costs of capacity. A drawback of a large expansion is that some of the capacity acquired is unlikely to be utilized for a long time. Given the high capital expenditures for capacity expansions, this implies a lower return on invested capital considering the time value of money. Equally important, such a large expansion is based on demand growth in the distant future which is more uncertain and may not materialize. For instance, Eskom, a power generator based in South Africa, committed to units of six 600 MW generators in the mid-1970s based on certain demand projections [5]. This resulted in an excess capacity of over 40% even after 15 years (i.e., in 1990) because the demand growth they had projected did not materialize and they had committed to irreversible contracts. On the other hand, it may be worthwhile to have significant excess capacity if the cost of lost sales is high and demand is very uncertain. This is the situation at Genentech [2] where the gross margin is high and there is considerable uncertainty about future demand for drugs, since they may or may not be approved for new uses. Similarly, when Nintendo launched the sales of Wii in late 2006, it was an instant hit and demand came from unexpected sources such as senior citizens. Nintendo's supply could not meet the demand, and there was a substantial supply shortage. The company had to expand its production capacity for the gaming console and had to make a critical capacity sizing decision [6]. If Nintendo substantially increased production capacity but the demand growth did not materialize, the company would absorb excess capacity cost and its profits would be impaired. However, if Nintendo underestimated the demand and did not expand its capacity enough, then the supply shortages and unmet demand would continue, possibly resulting in lost sales and customers.

Type

Capacity expansion planning also requires determining the types of resources to be added. We focus on two important aspects of the type of capacity: technology and flexibility. The technology of an equipment or facility determines several critical aspects of the products produced using that equipment: quality, speed, and unit cost. For instance, successive generations of computed tomography (CT) equipment have undergone revolutionary changes, with successive generations of equipment resulting in higher patient throughput and better image quality. Firms have to decide whether to buy the latest technology which may be more expensive and also whether to wait for some better technology. This is especially true in industries such as electronics where there is considerable technological change. Also, note that the size of the capacity additions is linked to the technology decision—large capacity expansions may not allow a firm to take advantage of frequent improvements in equipment technology.

Another important aspect of a resource type is the degree of flexibility of the resources in terms of their ability to produce different products, perform various tasks or operations. For example, an auto assembly plant may be able to assemble only one or multiple models of cars. Similarly, some flexible facilities are capable of producing a variety of different products. For instance, in the early 1990s, Eli Lilly had to decide whether to continue its past strategy of building dedicated capacity that could produce one product or adopt flexible facilities that could produce multiple products [7]. Flexible resources have the advantage of enabling a firm to adapt to fluctuations in demand for different products, thus increasing revenues and decreasing costs. However, they also require higher capital investments as flexible assets may be more expensive and may involve superior technologies. In some contexts, flexibility may require a more labor-intensive production process and this has implications for the type and size of capacity acquired as scale economies are very different in labor-intensive versus capital-intensive processes.

Location

In some contexts, firms have to make decisions about where to add capacity and in how many locations. Factors involved in making such location decisions are: customer locations, raw material supply locations, labor costs, transportation costs, exchange rates, tariffs, and so on. The focus of this article is not on location decisions; so we do not discuss this topic here (please refer to the section titled “Location Analysis” in this encyclopedia). But it is important to keep in mind that location issues are an important part of the capacity expansion decision. For instance, if shipping costs are substantially high, it is better for the firms to have capacities in multiple locations. For example, a soft drink producer will have numerous bottling plants as transportation costs are likely to be high. In this case, transportation costs between different locations need to be considered and minimized by determining optimal network configurations. If shipping costs are not as significant, firms can better utilize economies of scale by having capacity in a single location.

Alignment with Resources/Strategies

Organizations utilize many different types of resources and assets to perform various business activities at different stages of a production process. Capacity planning differs significantly depending on the type of production system and processes at a firm. In continuous flow processes such as steel mills, the production system is tightly integrated and capacity planning involves a simultaneous and proportional change in all the resources. On the other hand, in batch processes and job shops, capacity planning involves identifying appropriate capacity levels for different types of resources. For example, in apparel manufacturing, a firm will have to determine capacity levels of resources such as workers, cutting machines, dyeing capacity, and so on and this will vary with the type and mix of products produced. In such cases, capacity decision models usually assume that there is a single bottleneck (i.e., most utilized) resource, and capacity planning is based on this bottleneck resource. The facilities may be designed

around the bottleneck resource or stage, often the most expensive resource. In a job shop, such as a custom furniture manufacturer, capacity may be measured directly in terms of resource needs (number of lathes, saws, sanders, etc.) rather than products shipped.

Supply Chain Capacity Coordination

Capacity decisions often impact all the members of a supply chain, but each of these members may be independent entities. So, coordination and cooperation within the supply chain is important. In the Wii example cited earlier, some reports suggested that Nintendo could not produce enough consoles due to the tight supply of integral components such as IC chips and PCBs. Thus, even though Nintendo may have had sufficient assembly capacity, its suppliers did not have enough capacity to support their customer's production decision. This example illustrates the importance of coordination of the entire supply chain for capacity expansion. Ideally, capacity decisions need to be coordinated across a supply chain to prevent or reduce negative outcomes such as excess inventory, supply shortages, and congestion costs. Such issues are especially difficult to coordinate and manage in complex supply chains used to produce automobiles, apparel, and so on (see *Coordination of Production and Delivery in Supply Chain Scheduling* for additional details).

MODELS FOR CAPACITY PLANNING

Models are convenient ways to abstract reality and provide guidance for managers to make decisions. Several models have been developed to capture the main trade-offs in capacity expansion decisions and we present some of these models in the next few sections.

Deterministic Demand Models

In this section, we consider models where future demand is assumed to be known and in the next section, we consider uncertain future demand. While it may seem unrealistic to assume known future demand, we are really assuming a known demand forecast; so, it

is imperative that the use of such deterministic models be accompanied by substantial sensitivity or scenario analysis, as discussed in detail later. We assume that capacity shortages are not allowed unless specified otherwise. We now consider an infinite horizon model that captures the trade-off between making large capacity additions which result in lower purchase costs per unit of capacity versus small capacity additions, which result in a lower discounted cost of unused capacity (since early investments are more costly). Suppose demand is growing linearly over time at a rate of δ per year, that is, demand at time t is $D_t = \mu + \delta t$. Also, for convenience assume that capacity at time 0 is equal to μ . Then, at time 0, the firm will have to add capacity assuming they do not want any capacity shortages. Now, assume further that equipment or capacity purchased is infinitely durable. Suppose the same amount of capacity is added each time, and this amount is represented as x . Since demand is growing linearly at rate δ , note that $T = x/\delta$ is the time at which the next capacity addition will be made. At this time, again there will be no excess capacity and such a point is referred to as a *regeneration point*.

Let the cost of purchasing and installing capacity increment of size x be given by $g(x)$. Let the discount rate be " r " and so e^{-r} is the present value of a dollar at time t in the future. Let $C(x)$ denote the sum of all discounted future costs associated with purchase of current and future capacity increments. Since we have an infinite horizon problem, at every regeneration point, we will add a capacity unit x and the future costs are $C(x)$. We then have the following recursive equation

$$C(x) = g(x) + e^{-\frac{rx}{\delta}} C(x). \quad (1)$$

The first term on the right side of the equation is the purchase cost for the capacity increment installed now and the second term is the sum of all future capacity purchase costs discounted by the term $e^{-rx/\delta}$. Note that capacity additions of size x are made every time demand is equal to capacity, that is, at the regeneration point, and these occur at time intervals x/δ . From Equation (1), we

have

$$C(x) = \frac{g(x)}{\left(1 - e^{-\frac{rx}{\delta}}\right)}.$$

Example. If $g(x)$ is given by the power function kx^a where $k > 0, 0 < a < 1$, then

$$\frac{C(x)}{k} = \frac{x^a}{\left(1 - e^{-\frac{rx}{\delta}}\right)}.$$

Then the optimal $\hat{x}$ is obtained by differentiating $\log C(x)$ with respect to x and setting it equal to zero. We then have

$$\begin{aligned} \frac{d \log C(x)}{dx} &= \frac{a}{x} - \frac{\left(\frac{r}{\delta}\right) e^{-\frac{rx}{\delta}}}{\left(1 - e^{-\frac{rx}{\delta}}\right)} = 0 \\ \frac{\delta a}{r} &= \frac{\hat{x}}{\left(e^{\frac{r\hat{x}}{\delta}} - 1\right)}. \end{aligned}$$

Alternatively the optimal time $\hat{t} = \hat{x}/\delta$ between capacity additions is obtained by solving

$$\left(e^{r\hat{t}} - 1\right) = \frac{r\hat{t}}{a}.$$

For more general capacity cost functions, the optimal capacity additions can be obtained by a similar approach, that is, minimizing the discounted present value of capacity costs. While the linear demand function is easy to analyze and may represent reality in some contexts, note that the increase in demand is constant over time and does not increase as the total demand increases. In some contexts, total demand may grow at a constant percentage rate, that is, incremental demand is proportional to the volume. Such a demand pattern can be represented by $D_t = \mu e^{\delta t}$; note that demand growth is proportional to the demand volume at any point in time. Another demand function used in capacity models is

$$D_t = \beta(1 - e^{\delta t}).$$

This function represents demand with a decreasing growth rate over time, with a saturation level of β .

It has been shown [4] that the optimal policy is to add capacity at equal time intervals between expansions (although the size of each capacity addition may vary over time) when the capacity cost function is given by $g(x) = kx^a$ and demand is given by one of the three demand functions identified earlier or when cost function has a fixed plus variable cost structure, that is, $g(x) = F + vx$ and demand is increasing linearly.

Discrete-Time Model

The model presented in the previous section is a continuous-time model (i.e., demand, costs, etc. are computed continuously over time rather than at discrete-time points) which assumed a certain rate at which the demand varies over time. More flexible models allow demand to change at arbitrary rates over time and discrete-time models are used to represent such scenarios. We present a simple example of a discrete-time model next, assuming that the market is growing and only capacity additions are considered and shortages are not allowed. Let d_t, x_t , and I_t respectively denote the demand increment, capacity addition (or expansion), and excess capacity at end of period t ($t = 1, 2, \dots, T$). Note that d_t is the demand increment in a period and $d_t \geq 0$, so total demand is assumed to be nondecreasing over time. Let $f_t(x_t)$ denote the costs of purchasing and installing capacity and $h_t(I_t)$ the costs associated with excess capacity. The cost of capital or the appropriate discount factors are assumed to be incorporated in the functions $f_t(x_t)$ and $h_t(I_t)$ and are not identified explicitly. For simplicity, assume initial and final excess capacities are equal to 0. The formulation is

$$\begin{aligned} & \text{Minimize} \quad \sum_{t=1}^T (f_t(x_t) + h_t(I_t)) \\ & \text{subject to:} \quad I_t = I_{t-1} + x_t - D_t \quad \forall t \\ & \quad \quad \quad I_t, x_t \geq 0 \quad \forall t \\ & \quad \quad \quad I_0 = I_T = 0. \end{aligned}$$

While one could solve this problem directly as a nonlinear program, a simpler approach is to reformulate it as a dynamic program

(see the section titled “Fundamentals” in this encyclopedia) where the periods of the model are equivalent to the stages of the dynamic program. Let the state variable in the dynamic program be the excess capacity I_t . Let C_t denote the minimum total discounted cost during periods t through T . Then, the recursive equation is given by

$$\begin{aligned} C_t(I_t) = \min_{x_t} & (f_t(x_t) + h_t(I_t) \\ & + C_{t+1}(I_t + x_t - d_t)). \end{aligned}$$

While the dynamic program may be difficult to solve in general due to the curse of dimensionality, special cases of this formulation can be solved very efficiently. For instance, if the functions $f_t(x_t)$ and $h_t(I_t)$ are concave, the optimal solution is such that the capacity additions are equal to the demand increment in an integral number of periods, that is, $x_t = \sum_{\tau=1}^t d_\tau$. This dramatically reduces the state space and simplifies the solution approach. Furthermore, this model is equivalent to the economic lot sizing problem [8] (see also **Lot-Sizing**) and so many of the results obtained for that problem also apply here. This formulation and solution approach can be extended to incorporate negative demand increments, capacity disposals, capacity shortages, and so on [9]. This type of formulation has also been extended to consider discrete capacity sizes, capacity deterioration, multiple capacity types, and so on [9,10]. Also, such a formulation could be extended to consider the possibility of using the excess capacity to build inventory and carry it to future periods. Finally, in many real-world environments, equipment is not infinitely durable as we assumed earlier. So, equipment replacement decisions are often made together with capacity expansion decisions. The discrete-time model presented can be generalized to consider replacement together with capacity expansion decisions as discussed in Ref. 9.

The primary advantage of discrete-time models compared to the continuous-time models presented earlier is that they are more flexible in modeling the variation of demand over time. Also, various features of real capacity problems such as disposals and

shortages can be modeled easily. However, a drawback of deterministic models presented so far is that they do not explicitly consider the uncertainty in demand that is a key element of capacity expansion decisions.

Stochastic Demand Models

In this section, we consider models where future demand (or other parameters) is not known with certainty. In practice, many approaches have been proposed to deal with uncertainty such as decision trees, scenario planning [11], stochastic programming, and providing capacity cushions or buffers [10,12]. In the capacity cushions approach, we solve deterministic models with forecasted demands using the approach described in the section titled “Deterministic Demand Models” and use capacity buffers to deal with uncertainty. Such buffers can be computed using “newsvendor” type models [12] (see also **Supply Chain Coordination**) that trade-off the cost of lost sales with the cost of excess capacity. We do not discuss decision trees as they are similar in spirit to a special case of the stochastic programming approach discussed later in this section. Several models have been proposed that explicitly incorporate stochastic evolution of future demand and these require knowledge about the demand distributions. In this section, we discuss a basic model of this type.

An early seminal model to consider capacity expansion decisions when demand growth is probabilistic is due to Manne [1]. Manne was able to show that if demand follows a Brownian motion (see the section titled “Diffusion Processes and Random Walks” in this encyclopedia) with positive drift and capacity shortages are not allowed, then the stochastic model is equivalent to a deterministic model with a lower discount rate. Let us consider this model which assumes an infinite horizon. As in the deterministic case, let the cost of purchasing and installing capacity increment of size x be given by $f(x)$, discount rate be “ r ” and $C(x)$ denote the sum of all discounted future costs associated with the purchase of current and future capacity increments. Let the demand process be represented by a Brownian motion with the drift parameter

μ and variance σ^2 ; that is, demand is random and the demand increment at any time t is a random variable which is normally distributed with mean μt and a variance $\sigma^2 t$ [1]. We assume that capacity shortages are not allowed and capacity can be added instantaneously, that is the lead time for adding capacity is zero.

Manne shows that this stochastic capacity expansion problem can be written as the following problem

$$C(x) = f(x) + \int_{t=0}^{t=\infty} u(t, x) e^{-rx} C(x) dt, \quad (2)$$

where $u(t, x) dt$ is the probability that t is the time difference between two successive capacity additions (or regeneration points) between which total demand grows by x units. Manne further shows that

$$\int_{t=0}^{t=\infty} u(t, x) e^{-rx} C(x) dt = e^{\lambda x},$$

where $\lambda = \frac{\mu}{\sigma^2} \left(1 - \sqrt{\frac{1+2r\sigma^2}{\mu^2}}\right)$. Hence, the recursive Equation (2) simplifies to

$$C(x) = \frac{f(x)}{(1 - e^{\lambda x})}. \quad (3)$$

Comparing Equations (1) and (3), the stochastic problem is equivalent to the deterministic problem (1) with λ replacing $-r$, that is the negative of the discount rate r . It is straightforward to see from the expression for λ that an increase in the variance σ^2 results in a higher value of λ (note that λ is negative), that is, a smaller adjusted discount rate. Two important observations then follow: an increase in the variance σ^2 will result in higher costs $C(x)$ and the optimal capacity increment $\hat{x}$ will be larger. Thus, greater variance in the demand process results in larger capacity acquisitions.

Several subsequent articles have shown that this important transformation holds under more general conditions. Bean *et al.* [13] showed that if demand is a transformed (nonlinear) Brownian motion or a regenerative birth-and-death process (see the section

titled “Stochastic Processes” in this encyclopedia), then the problem can be transformed to an equivalent deterministic problem with a lower adjusted discount rate. It may be difficult in reality to estimate exactly the adjusted discount rate for the regenerative birth-and-death process as it requires knowledge of the complete distribution of the first passage time in the underlying process. But Bean *et al.* [13] point out that a very good second-order approximation of the discount rate can be obtained using only the coefficient of variation of the demand process. Furthermore, they point out that when the coefficient of variation is small, the adjusted discount rate is only slightly lower than the unadjusted discount rate. In such situations, it may not be costly to ignore the effects of demand uncertainty in making capacity decisions. However, if the demand variation is high, then it is critical to consider the impact of demand uncertainty.

Appropriate discount rate “r”: even in a deterministic problem, as Luss [4] points out, “since the planning horizon for capacity expansion problems is usually long, it is virtually impossible to forecast the *appropriate* discount rate over that period.” This issue becomes even trickier in a stochastic environment as we have to adjust the discount rate downwards to account for demand variance as observed earlier. Furthermore, technological changes impact future capacity purchase and operating costs, often resulting in lower costs. This can be incorporated by adjusting the discount rate appropriately but since effects of technological changes are difficult to forecast over long periods, it is difficult to estimate the appropriate adjustments to the discount rate. Therefore, extensive sensitivity analysis studies are common in capacity planning decisions. Next, we provide a systematic approach to capacity planning that is based on considering various future scenarios.

Stochastic Programming Model

An alternative approach proposed to deal with uncertainty in demand and other parameters is a stochastic programming based approach, which uses scenarios to model the uncertainty within large-scale mathematical programs. The advantage of

these approaches is that one can consider fairly general models wherein multiple resources used to make multiple products can be considered. Also, one could potentially consider scenarios incorporating different possible future realizations of demand, costs, and so on. The drawback of these approaches is that one does not obtain analytical solutions for the optimal capacity size and the problem size grows substantially with the number of scenarios considered which makes it difficult to solve the problems. We describe a generic version of the approaches proposed in Refs 11,14–16—we focus on one resource producing one product to keep the exposition simple. It is straightforward to extend the approach to multiple resources and products, although it increases the problem size and the corresponding difficulty in solving the model. The model is similar to the discrete-time model presented earlier except that we use different scenarios for demand and we use a fixed plus variable cost function for capacity costs. Also, such models incorporate production decisions where production takes place after demand is known and production is constrained by capacity acquisition decisions which are made before the demand is known.

We define variables x_t^s for capacity purchased, y_t^s for production level, and I_t^s for excess capacity in period t under scenario s . Let z_t^s denote a binary variable equal to 1 or 0 depending on whether or not capacity is purchased in period t in scenario s . The capacity acquisition costs comprise of fixed costs $f_t^s z_t^s$ and variable costs $v_t^s x_t^s$, excess capacity costs are $h_t^s(I_t^s)$ and the production costs are $c_t^s(y_t^s)$ corresponding to period t and scenario s . A scenario s corresponds to a particular realization of the parameters and p_s is the probability of scenario s ($\sum_{s=1}^S p_s = 1$). However, note that parameters get realized incrementally over time. So we have a scenario tree where the nodes at stage (or level) t of the tree, denoted as B_t , constitute the states of the world or scenarios, say $s_i \in B_t$, that can be distinguished by information available up to time stage t (we do not add an index t to s_i to keep the notation simple). Therefore, in the formulation below, s, s_i , and s_j all represent

different scenarios. The formulation is

Minimize

$$\sum_{s=1}^S p_s \left(\sum_{t=1}^T (f_t^s z_t^s + v_t^s x_t^s + c_t^s (y_t^s) + h_t^s (I_t^s)) \right) \quad (4)$$

subject to:

$$I_t^s = I_{t-1}^s + x_t^s - D_t^s \quad \forall t, s \quad (5)$$

$$y_t^s \leq \sum_{\tau=1}^t x_\tau^s \quad \forall t, s \quad (6)$$

$$x_t^s \leq M z_t^s \quad \forall t, s \quad (7)$$

$$z_t^{s_i} = z_t^{s_j}, x_t^{s_i} = x_t^{s_j}, y_t^{s_i} = y_t^{s_j}, I_t^{s_i} = I_t^{s_j} \quad \forall (s_i, s_j) \in B_t, i \neq j, \forall t \quad (8)$$

$$z_t^s \in \{0, 1\}, x_t^s, I_t^s, y_t^s \geq 0 \quad \forall t, s. \quad (9)$$

Constraint (5) is the excess capacity balance constraint. Constraint (6) enforces the condition that the production level in a period does not exceed the installed capacity. Constraint (7) ensures that capacity is added in period t in scenario s only if $z_t^s = 1$ (where M is a large number). At time t , the decision maker cannot distinguish between two scenarios s_i and s_j that belong to the same node B_t of the scenario tree. Consequently, the decisions corresponding to scenarios s_i and s_j have to be identical and this is imposed through the constraints (8), which are referred to as *nonanticipativity* constraints in Ref. 17. Nonnegativity and binary restrictions of the variables are enforced through (9).

Note that this problem is a stochastic mixed integer linear programming problem and is therefore difficult to solve. Hence, heuristic solution approaches are proposed and we briefly summarize the heuristic approach proposed in Ref. 14 as an example of a typical approach, although there are variations in the models and corresponding solution approaches proposed. In the first phase, the integrality constraints are relaxed and so we have a large stochastic linear program which can be solved using a variety of approaches developed specifically for large-scale linear programs. If this solution is also integral, then we have the optimal solution. Otherwise, in the second phase,

the *nonanticipativity* constraints are relaxed and this results in S instances of the deterministic capacity expansion problems, which can be solved optimally using conventional approaches such as the Wagner–Whitin procedure [8], if the subproblems are simple (e.g., single resource, single product with continuous capacity purchases possible) or more complex approaches depending on the nature of the subproblems. If these solutions to the subproblems satisfy the *nonanticipativity* constraints, then we have the optimal solution. Otherwise, we go to the third phase, wherein the solution obtained in the second phase is heuristically modified to ensure that it satisfies the *nonanticipativity* constraints. Ahmed and Shinidis [14] show that this approach works quite well. Huang and Ahmed [16] generalize and improve upon this approach by exploiting properties of the subproblems. They provide an efficient approximation scheme and an asymptotic optimality guarantee for the approximation scheme. So, it appears that the stochastic programming approach is potentially attractive in solving capacity expansion problems and one can expect further refinements and improvements in these approaches.

Most of the literature in this area has focused on capacity expansion in scenarios with demand growth. In reality, demand may decline too and capacity may have to be decreased. In many industries, the salvage value of capacity is often negligible, that is, only a fraction of the investments in capacity can be recovered if the facilities are sold. This is primarily for two reasons. First, investments may be firm-specific in which case there is no clear market value for the assets. Second, if the assets are more general-purpose, firms will often try to dispose of assets when industry demand is low and likely to remain low in the near future, but in those circumstances, other firms are facing the same industry conditions and so demand for such capacity is low and this leads to low salvage values for the assets. In scenarios where demand may rise or decline due to economic cycles, firms may invest, stay put or disinvest—Eberly and Van Mieghem [18] refer to this as an Invest/Stay put/Disinvest (ISD) policy and show that such a policy is

optimal when the operating profit functions are concave. Such a policy involves computing two triggers, say L_t and H_t , which are functions of the problem parameters and the following three action zones in each period t : (i) Invest, that is, increase in current capacity to L_t if it is less than L_t ; (ii) Stay put, that is, no action is taken if current capacity is between L_t and H_t ; (iii) Disinvest, that is, decrease in current capacity to H_t if it is greater than H_t . The width of the region $(H_t - L_t)$ is called a *hysteresis zone* and increases with the amount of irreversibility in investment costs, level of fixed costs of capacity adjustment, and indivisibility or lumpiness in capacity purchases and disposal.

SHELF SPACE ALLOCATION

Problem Description

Retail stores have a limited amount of space and many products to display. The amount of shelf space allocated to an item affects its frequency of replenishment, incidence of stockouts, and demand rate. Therefore, finding the optimal amount of shelf space to allocate to each item becomes a key factor for success. Effective shelf space allocation leads to higher profits by increasing sales and customer satisfaction, creating better product visibility and brand exposure, and reducing inventory-related costs and stockouts [1–3]. Indeed, effective shelf space allocation has become harder and more critical in recent years because of increases in product variety and competition. For instance, on average, the number of consumer-packaged stock keeping units (SKUs) in the marketplace increased by 16% per year between 1985 and 1992, whereas shelf space expanded by only 1.5% per year during the same period [4]. A modern conventional supermarket offering major food departments, nonfood grocery, and limited general merchandise products has 20,000 to 30,000 sq. ft of floor space and it carries 20,000 to 40,000 SKUs [[1], p. 40].

Shelf space allocation is the process of apportioning the amount of space to each product in order to maximize the total store profit or another well-defined objective function subject to limited store space and other financial and operational constraints. Shelf space is usually measured in linear terms

such as the number of *facings* and the length of each facing. The depth of a shelf and the dimensions of an item are also used in order to compute the shelf capacity allocated to each item.

Researchers from marketing, operations management, and other related fields have been developing tools and techniques for more effective shelf space allocation [5]. From a marketing perspective, the visual appeal of the display, the amount of product variety, and the location of each item in the store are important in order to maximize total sales. In particular, researchers define a metric called the *shelf space elasticity* of demand as the ratio of relative change in unit sales to relative change in shelf space. They measure shelf space elasticity for various types of products to evaluate the effect of display on sales. The key factors from an operations perspective are demand estimation, shelf replenishment frequency, inventory holding cost, the cost of stockouts, replenishment-related labor time and cost, and the impact of case pack sizes on inventory management policies. The operations perspective is more relevant for supermarkets, convenience stores, drug stores, and discount retailers because operational efficiency can lead to lower costs, which, in turn, increases competitiveness. The marketing issues are dominant for other types of retailers such as apparel stores in which the visual appeal of the display has a substantial demand-stimulating effect. Conflicting interests of the marketing and operations strategies also pose challenging questions.

In this article, we describe the measurement of shelf space elasticity of demand, the mathematical models and heuristic approaches to allocate shelf space, and commercial packages used in the industry.

Measurement of Shelf Space Elasticity

The amount of shelf space allocated to a product influences its unit sales. In one of the earliest studies on shelf space allocation, Cairns [[6], p. 43] states that “the more space

allocated to an item, the more likely it is to be seen by a shopper and, hence, the more likely it is to be purchased.” However, the shelf space elasticity of demand can vary across products. Brown and Tucker [7] identify the following three classes of products with varying shelf space elasticity of demand:

1. Unresponsive products, for which changes in shelf space allocation have no impact on sales rate (e.g., salt and spices). These products are also generally price inelastic.
2. General use products, for which increasing shelf space leads to increase in sales but at a diminishing rate (e.g., breakfast foods and canned fruit and vegetables).
3. Occasional purchase products, for which shelf space has a step-function or threshold effect on sales. Sales increase slowly with shelf space at first, until a large display causes a steep increase in sales to a point of diminishing returns. These include impulse buys (e.g., candy).

Following Brown and Tucker [7], researchers have sought to measure shelf space elasticity for various types of products. Both retailers and manufacturers are interested in this measurement, but for different reasons. Retailers care about total profits across all products. They benefit because they can allocate different amounts of shelf space to different products depending on their space elasticities and gross margins. Manufacturers care about the profit from their own products. They benefit because they can build shelf space allocation into their merchandizing discussions with retailers. For example, it has been found that private-label or store-brand products have higher shelf space elasticity than competing national brand products [8]. Thus, an easy way for a retailer to shift sales from national to store brands is to give more space to store brands on its shelf display.

Among early works in this area, Kotzan and Evanson [9] have conducted an experiment at a drug store chain to evaluate the impact of changes in shelf space on

unit sales. Their experiment was conducted on four products that met certain criteria related to demand uncertainty and availability of inventory. These products were tested in three stores for three weeks, where the number of facings allocated to each product was changed each week from 1, 2, or 3 facings. The authors discovered that three of the four products, a family-size Crest toothpaste, Hook’s Red Mouth Wash, and Johnson and Johnson Assorted Band Aids, had statistically significant positive shelf space elasticities. For example, the sales of Crest toothpaste with 1, 2, and 3 facings were 219, 291, and 294 tubes, respectively. The results for the fourth product (Preparation H Suppositories) were inconclusive.

Kotzan and Evanson did not investigate why shelf space elasticity varied across these products. However, the academic literature suggests many reasons for such variation. For instance, Curhan [8] relates shelf space elasticity to product characteristics. He hypothesizes that items with smaller package sizes, lower prices, smaller market shares, private-label brands, and higher sales rates (i.e., fast moving items) would have higher shelf space elasticities. He also hypothesizes that greater product variety, more availability of substitutes, and lower repurchase frequency would lead to higher shelf space elasticities. He tests these hypotheses by conducting an experiment for grocery products in supermarket stores. In this experiment, shelf space is changed for 500 items and their unit sales are observed for 5 weeks before the change and 12 weeks after the change. Shelf space elasticity is measured as the ratio of percent change in unit sales to the percent change in shelf space. Curhan [8] obtains very low R^2 values. He concludes that the product characteristics do not satisfactorily explain the observed variation in shelf space elasticities because the impact of shelf space on unit sales is very small relative to the effects of other environmental variables, leading to a failure of the model. Nonetheless, the average space elasticity across all items in his dataset is 0.212, showing a positive effect of shelf space on sales. In another study, Frank and Massy [10] show that environmental

variables such as store size, number of shelf rows, and shelf levels have a substantial impact on sales. Cox [11] also conducts an in-store experiment and provides evidence that staple product brands (e.g., salt brands) and impulse product brands that have low consumer acceptance are unresponsive to changes in shelf space. On the contrary, sales of an impulse product brand that has high consumer acceptance (e.g., Coffeemate) increase in shelf space.

Various conclusions are drawn in the literature from this early research. One is that shelf space elasticity is difficult to measure because a retail store is a dynamic environment and it is almost impossible to control factors such as retail prices, advertising, and addition and deletion of products, which have direct effects on sales [12,13]. Another is that shelf space elasticity is not large enough in magnitude to be managerially relevant. Instead, shelf space allocation should emphasize operational considerations such as the labor cost of restocking shelves and avoidance of stockouts. On the positive side, it is well recognized that shelf space elasticity varies across products, and is more important for private-label products and impulse-purchase items.

Research has also addressed how shelf space elasticity can be used by a retailer to increase sales and profits. For instance, Anderson [14] models the relationship between a product's market share and its share of shelf space using a logistic regression in order to find the profit-maximizing shelf space allocation. Dreze *et al.* [15] conduct experiments comparing two types of shelf management at a supermarket chain. In the first of these experiments, they change the shelf space allocation for each product to be proportional to the historical sales rate of the product in similar stores. Thus, in this method, they customize shelf space allocation in each store according to its historical sales. They note that this contrasts with the existing practice, which allocates shelf space in all stores of the chain identically regardless of differences in their sales mix. In these authors' second experiment, they reorganize the planogram for the store to facilitate cross-category merchandizing by

placing complementary product categories closer to each other. The experiment shows a 4% increase in sales and profits due to customized shelf space and 5–6% increase due to planogram reorganization. They use the results of their experiment in an optimization model and estimate that there is a potential for 15% increase in sales by optimizing the shelf space allocation to each item using the estimated parameters. They conjecture that the increase in sales is driven by customers increasing their share of purchases at the subject supermarket store when they are presented with a better shelf space allocation.

Thus, we see that experiments have been widely used to study shelf space allocation. Next, we turn our attention to using the results of such experiments in optimization models.

Optimization Models

We explain the optimization of shelf space using a model given by Corstjens and Doyle [13]. This model has been widely used and improved upon since 1981. We summarize some of the later developments after presenting the model.

Consider a retailer with total available shelf space S^* . The retailer seeks to allocate this space among K products in order to maximize its total profit. Let s_i be the shelf space allocated to product i , β_i be the direct elasticity of sales of product i with respect to its shelf space s_i , and δ_{ij} be the cross-space elasticity of the sales of product i with respect to the shelf space s_j allocated to product j . δ_{ij} can be positive or negative, and need not be equal to δ_{ji} . Then, the total sales for product i are written as

$$q_i = \alpha_i s_i^{\beta_i} \prod_{j=1, \dots, K, j \neq i} s_j^{\delta_{ij}}. \quad (1)$$

The gross margin from product i is written as $w_i q_i$, where w_i is the percent gross margin, and the variable store expense for product i given the sales quantity is written as $C_i = \gamma_i q_i^{\tau_i}$, where τ_i is the operating cost elasticity associated with the sales of product i . The retailer seeks to maximize its total profit, which is equal to the difference between the total gross margin and the total variable store

expense. This problem is formulated as the following constrained nonlinear program:

$$\begin{aligned} \max \sum_{i=1}^K w_i & \left[\alpha_i s_i^{\beta_i} \prod_{j=1, \dots, K, j \neq i} s_j^{\delta_{ij}} \right] \\ - \sum_{i=1}^K \gamma_i & \left[\alpha_i s_i^{\beta_i \tau_i} \prod_{j=1, \dots, K, j \neq i} s_j^{\delta_{ij} \tau_i} \right] \quad (2) \end{aligned}$$

subject to

$$\sum_{i=1}^K s_i \leq S^*, \quad (3)$$

$$\alpha_i s_i^{\beta_i} \prod_{j=1, \dots, K, j \neq i} s_j^{\delta_{ij}} \leq Q^* \quad i = 1, \dots, K, \quad (4)$$

$$s_i^L \leq s_i \leq s_i^U \quad i = 1, \dots, K, \quad (5)$$

$$s_i \geq 0 \quad i = 1, \dots, K. \quad (6)$$

Here, the first constraint represents the upper limit on available shelf space in the retail store. The second constraint represents an upper limit on the amount of sales that can be achieved for each product in the store. The third constraint restricts the amount of shelf space that can be allocated to each item to lie between two control limits.

This problem is extremely difficult to solve because the objective function and one of the constraints are nonlinear. Corstjens and Doyle [13] use a geometric programming method to solve this problem. They illustrate their model using data from a retail chain selling various types of candy, ice cream, and greeting cards. First they obtain data on sales and facings for each product across 140 stores. They fit equation (1) to each product category to estimate the direct and cross-shelf space elasticities. They also obtain cost data from the management to estimate gross margin and variable store expenses. They then optimize shelf space using these estimated parameters. The results lead to substantial changes in shelf space allocation from the existing allocations. For example, the results show that the optimal allocations for large and small stores differ from each other due to variation in sales mix. Thus, the model incorporates direct and cross-space elasticities, profit margins, and operating

costs to improve shelf space allocation. Corstjens and Doyle [16] later introduced a dynamic version of this model. It is a multiperiod model that takes into account anticipated changes in customer preferences and sales growth and decline of products. This model presents a long-term strategic view that encourages retailers to sacrifice short-term profits in order to maximize profits in the long run by taking shelf space away from declining products and allocating it to products with high growth potential. The optimization model of Corstjens and Doyle [13] has been further improved upon in subsequent research using many techniques, such as marginal analysis [17], dynamic programming [18], generalized Lagrange multiplier methods [19], and multistage optimization [20].

Most of the mathematical shelf space allocation models are nonlinear, mixed-integer problems that are computationally expensive for moderate-sized cases; even linear versions of this problem are NP-hard [2]. These difficulties have generated interest in heuristic solution approaches for these problems. For example, Urban [21] proposes a greedy heuristic to solve a nonlinear mixed-integer shelf space allocation problem. His algorithm starts with an initial solution including all items in the assortment plan. It then iteratively removes one item at a time from the assortment based on the greatest improvement in net profit estimated using a generalized reduced gradient. The algorithm stops when net profits cannot be improved any further by removing another item. Other techniques such as genetic algorithms [21–23], knapsack heuristics [24], local search methods [2], goal programming [25], simulated annealing [26], and greedy heuristics [27] are also used to solve shelf space allocation problems. In short, methods that are used to solve nonlinear programs can be tailored to solve shelf space allocation problems.

Another important consideration in shelf space allocation is its effect on inventory costs. Two items differing in shelf facings and/or service level requirements will have different inventory costs. For instance, an item with less shelf space will have more frequent stockouts and replenishments, which

will lead to higher stockout and labor costs, *ceteris paribus*. The shelf space allocation models that we have discussed thus far assume that the shelves are always fully stocked. Thus, they do not address the role of inventory costs on shelf space allocation. Freund and Matsuo [28] study this aspect by modeling inventory replenishment as a periodic order-up-to policy and explicitly defining holding costs, review costs, and stockout risk. They show that the importance of considering inventory costs increases as the desired service level increases. Furthermore, they conclude that higher service level requirements force the retailer to have a smaller assortment because the net profit suffers due to high operating costs when there is a wide product variety.

In many retail stores, inventory is split into “display inventory” and “backroom inventory.” Urban [21] distinguishes between the backroom and displayed inventories by tracking them separately. In his model, demand is a function of displayed inventory, whereas the backroom inventory allows the retailer to achieve economies of scale by ordering more than the shelf capacity and storing the excess units in the backroom. Thus, a backroom allows the retailer to stock more SKUs. Maiti and Maiti [23] adopt a similar framework. They provide a contractive mapping genetic algorithm to simultaneously solve the inventory management and shelf space allocation problems. See Urban [29] for an overview of the interdependencies between the inventory and shelf space allocation decisions.

Hwang *et al.* [22] analyze a model in which the demand rate is a function of the display location and quantity displayed. Their model determines shelf space allocation, order quantities, and the location where each brand should be displayed. Recent research by K  k and Fisher [30] has focused on integrating not only shelf space allocation and inventory decisions but also product assortment decisions in a single model. They determine what products should be selected to be put in the assortment and how much shelf space should be allocated to each item given inventory costs, product substitution, and shelf space constraints. They implement

their results at a supermarket chain. It is noteworthy that earlier researchers have also sought to integrate shelf space allocation and assortment decisions into one model. For example, Anderson and Amato [31] determine product assortment and shelf space allocation decisions jointly, but without considering inventory costs.

Commercial Software

Early commercial software such as PRO-GALI, OBM, CIFRINO, SLIM, COSMOS, and HOPE are based on simple rules of thumb such as allocating more space to products with the highest average sales or profit margins. None of these tools explicitly considers elasticities [16–18]. The next-generation commercial solutions are hybrid knowledge-based systems that can integrate human expertise and algorithmic techniques. One of the earliest hybrid knowledge-based decision support systems (DSS) used for shelf space allocation is Resource-opt [32]. It takes past sales, market research information, and managerial intuition as user input and extends Corstjens and Doyle [13] to provide store managers with a user-friendly DSS. It has been utilized to redesign a hypermarket in France, and perform shelf space allocation for three departments of a Scandinavian store as well as an oil company’s 2000 store franchise in Europe.

Presently it is common practice to use software assistance to generate visual diagrams (planograms) that show where every product in a retail store should be placed. For instance, PC-based systems such as Appollo (IRI) and Spaceman (Nielsen) are widely used at a strategic level. However, their operational level use is still very restricted due to their limited decision support functionality [20]. Generic optimization software packages such as LINGO (LINDO Systems) can be used at a tactical and/or operational level once the shelf space allocation problem is modeled as a nonlinear program [33].

Discrepancies occurring due to the use of planograms pose another problem as store managers have a tendency to deviate from recommended allocations. Most large retailer chains design planograms at the corporate level and give local store managers

some degree of freedom to modify the recommended design. Incentives for store managers are frequently tied to stockouts on the shelf and discipline in adhering to the shelf space allocation decided by the corporate office. However, managers also need to consider other issues such as the sales effect of fully stocked shelves and holding labor and replenishment costs (most of which are not captured by high level planograms). Furthermore, they need to react to local campaigns run by competitors. van Woensel *et al.* [34] analyze the possible causes for discrepancies between the recommended planograms and actual allocations and discuss the negative impact of these deviations on marketing efforts and operational efficiency.

Moreover, since shelf space is a scarce resource, it is natural for competing suppliers to try to influence the retailers' allocation decisions via negotiations and contract terms in order to obtain more shelf space. Martin-Herran *et al.* [35] model the interaction between two suppliers and a retailer as a Stackelberg game where two suppliers are leading and competing for the follower's (i.e., the retailer's) shelf space. They focus on the effect of the suppliers' advertisement strategies and show that the Stackelberg open-loop equilibrium is time-consistent.

In conclusion, researchers have been addressing various aspects of the shelf space allocation problem for more than 40 years. However, other issues remain to be addressed, such as the impact on shelf space management of the introduction of new tools and techniques for inventory management (e.g., RFID tags, contracting, and vendor managed inventory systems), poor processes for replenishment from backroom to shelf, inventory data inaccuracy, and misplaced SKUs [36,37].

MODELS WITH INVENTORY DEPENDENT DEMAND

Problem Description

In classical inventory models, we minimize inventory-related costs under the assumption that the demand is exogenous. However, in retailing, where the inventory

is visible to the end consumer, the rate of demand is often increasing in the amount of inventory stocked. As mentioned in the previous section, displayed stocks can stimulate demand [13]. Similarly, Wolfe and Little [38] provide evidence that the sales of style merchandise goods such as women's dresses are proportional to the amount of inventory displayed. In fact, the concept of psychic stock, defined as retail display inventory for stimulating demand, is motivated by the prevalence of this effect [39]. The demand-stimulating effect of inventories has motivated research to determine optimal inventory levels by solving the trade-off arising from the benefits and costs of holding more inventories. Early studies in the literature focus on developing inventory models for items with inventory-level-dependent rates. Recent literature has started to address strategic and tactical issues.

Economic Order Quantity Type Models and their Extensions

Economic order quantity (EOQ) type models are used to determine the optimal inventory policy when the demand is deterministic and influenced by inventory. We follow the research paper by Balakrishnan *et al.* [40] to introduce such models. Let the demand rate vary continuously as a function of the current inventory. If I denotes current inventory, then the demand rate is written as a nondecreasing concave function of I , denoted as $\lambda(I)$. For example, $\lambda(I) = \alpha(I + \phi)^\beta$, where $\alpha > 0$ is a scaling constant, $0 < \beta \leq 1$ is called the inventory elasticity of demand, and ϕ is a nonnegative base demand factor.

The mechanics of the model are as follows. Let $\hat{I}$ denote the inventory at the beginning of a replenishment cycle and T denote the length of the replenishment cycle. Inventory depletes at the rate of demand during the cycle. The inventory level at any time t during the cycle is obtained by integrating the inventory balance equation, $dI(t)/dt = -\lambda(I(t))$. For example, if $\lambda(I) = \alpha I^\beta$, then the inventory at time t is equal to $I(t) = (\hat{I}^{1-\beta} - \alpha t)^{1/(1-\beta)}$. Let $D(\hat{I}, T)$ denote the total demand during the replenishment cycle. It is equal to the difference between $\hat{I}$ and $I(T)$. The length of the

replenishment cycle must be smaller than the time taken to deplete all the inventory. Let $T_{\text{runout}}(\hat{I})$ denote the time at which inventory will run out if not replenished.

The firm seeks to determine the order-up-to level $\hat{I}$ and the replenishment interval T in order to maximize its average profit per unit time. Let h denote the inventory holding cost rate, S the ordering cost, and r the per unit profit contribution. The profit per unit time is given by

$$\pi(\hat{I}, T) = \frac{1}{T} \{rD(\hat{I}, T) - S\} - h\bar{I}(\hat{I}, T), \quad (7)$$

where $\bar{I}(\hat{I}, T)$ is the average inventory per unit time and can be written as

$$\bar{I}(\hat{I}, T) = \frac{1}{T} \int_0^T I(t)dt = \hat{I} - \frac{1}{T} \int_0^T D(\hat{I}, t)dt.$$

The firm's demand-stimulating inventory problem, thus, involves maximizing (7) subject to the constraint that $T \leq T_{\text{runout}}(\hat{I})$. This problem differs from the EOQ problem because it entails profit maximization rather than cost minimization and it allows replenishment to take place when the inventory is not fully depleted. Indeed, Balakrishnan *et al.* [40] distinguish two types of products depending on the optimal policy: early-replenishment products are those for which $T < T_{\text{runout}}(\hat{I})$ and runout-replenishment products are those for which the constraint is binding.

We illustrate the optimal solution obtained by Balakrishnan *et al.* [40] for a specific demand function which they call the reference demand model. In this model, the inventory elasticity of demand is equal to 0.5 and the demand rate is specified as $\lambda(I) = \alpha\sqrt{I} + \phi$. This yields the cumulative demand function $D(\hat{I}, t) = \alpha t\sqrt{\hat{I} + \phi} - (\alpha t/2)^2$ and $T_{\text{runout}}(\hat{I}) = (2/\alpha)(\sqrt{\hat{I} + \phi} - \sqrt{\phi})$. Substituting these expressions into the profit function and solving for the optimal $\hat{I}$ and T , we find that the early-replenishment strategy gives the optimal solution if the ordering cost S is below a certain threshold and the runout-replenishment strategy is optimal otherwise. The optimal replenishment cycle

and order-up-to level for early-replenishment products are obtained as

$$T^* = 2 \left(\frac{3S}{\alpha^2 h} \right)^{1/3}$$

and

$$\hat{I}^* = \frac{\alpha^2}{4} \left(\frac{r}{h} + \left(\frac{3S}{\alpha^2 h} \right)^{1/3} \right)^2 - \phi.$$

The optimal order-up-to level for runout-replenishment products is obtained similarly.

Many insights can be obtained from this solution. As in the classical EOQ model, in this model T^* depends on the ratio S/h . Moreover, T^* does not depend on r . Thus, as in the EOQ model, the length of the replenishment cycle is determined by the trade-off between the ordering cost and the holding cost. The optimal order-up-to level, however, depends on r/h . Hence, it is determined by the trade-off between the contribution and the holding cost. When the contribution increases, the replenishment cycle remains unchanged, but the firm carries more inventory and places its orders at higher reorder points. Balakrishnan *et al.* [40] also construct a heuristic and refer to it as the adaptive EOQ policy. In this heuristic, the firm uses the EOQ formula to determine the order quantity in each cycle, but recalibrates the demand rate parameter λ using the observed average demand rate in the previous cycle. This heuristic differs from the optimal policy because it does not allow orders to take place before the inventory runs out. However, it enables the firm to learn about the dependence of demand on inventory from historical data. Balakrishnan *et al.* [40] show that this heuristic converges to an equilibrium order quantity. However, it performs poorly because (i) it waits for the inventory to run out before placing a reorder and (ii) in each cycle, it orders too little and too frequently. For example, their analysis shows that, if $\lambda(I) = \alpha I^{0.5}$ and the product is an early-replenishment product, then the profit from the adaptive EOQ policy is always less than 40% of the optimal profit.

The demand function $\lambda(I) = \alpha I^\beta$ is appealing because it is similar to functions used to model the dependence of demand on shelf

space [13]. This functional form makes the parameter estimation relatively easy because we can do a logarithmic transformation and fit a linear regression model to estimate α and β . It is possible to use many similar functional forms in a model to capture the demand-stimulating effect of inventory. Gupta and Vrat [41] assume that the demand rate depends only on the initial inventory, and remains constant at this rate. Baker and Urban [42] and Urban [43] allow demand to vary continuously with inventory and show that it may not be optimal to wait to place an order until the inventory level reaches zero. Urban [44] gives a recent survey of the literature on this topic.

Modeling the inventory dependent demand for perishable items require an additional structure since demand for a perishable item decreases not only with inventory but also due to loss of product freshness and/or an approaching expiration date. Such models have been studied in the literature [45–48]. For example, Balkhi and Benkherouf [48] model demand as $\lambda(I, t) = I^\beta G(t)$, where I is the current inventory, t denotes time, and $G(t)$ is an increasing function of time, and the inventory is allowed to deteriorate continuously over time at a fixed rate θ . Instead of deterioration of inventory, another feature to consider in certain situations is that the value of the unsold inventory may decrease over time [49]. This happens for seasonal or fashion products.

Strategic and Tactical Implications

Strategic consumers indirectly observe retailers' inventory policies over time. If a consumer's observations lead her to believe that she has a low probability of finding a desired product at a given retailer, she might choose to shop at a competitor instead. For instance, Anderson *et al.* [50] present empirical evidence showing that consumers who experience a stockout are less likely to place an order; these consumers also order fewer items, and spend less. These authors also show that the retailer might be able mitigate the cost of a stockout if an item is out of stock due to high popularity as consumers are more willing to backorder

scarce items. On the contrary, consumers may be willing to pay a premium price for consistently high service rates. For instance, Dana [51] describes a small experiment on video stores and argues that Blockbuster's advertised claims of high availability allow the retailer to charge higher prices. These empirical results show that the retailer's stocking decisions and ability to manage stockouts shape its reputation which affects its future demand and pricing power.

Dana and Petruzzi [52] present a model in which consumers form beliefs about the service level offered by a retailer. They then decide whether to visit the retailer based on these beliefs. This model describes a single period, which can be interpreted as a steady-state representation of a repeated game between the consumers and the retailer. Their analysis shows that, when the retailer recognizes the effect of its service level on demand, it stocks higher inventory levels. As a consequence, the retailer attracts more customers and earns a higher expected profit. Similarly, many models have been developed in the recent research describing consumers who behave strategically by deciding when to visit a given retailer. Their strategic behavior can be affected by product availability, expectation of markdowns, and so on. We do not describe these models in this article, since they form a large body of literature by themselves.

Overlooking the demand-stimulating effect of inventory also creates incentive misalignment issues in retail operations, as most of the automated inventory replenishment systems try to minimize inventory-related costs whereas store managers are assessed on revenues. van Donselaar *et al.* [53] empirically show that retail stores managers have a tendency to deviate from order advices generated by an automated inventory replenishment system. Their analysis illustrates that the store managers improve the automated replenishment system's performance by systematically modifying the order advices because they are able to capture the demand-stimulating effect of inventories which is ignored by the system. Similarly, Kesavan *et al.* [54] estimate the effect of gross margin and inventory on

each other and empirically show that more accurate firm level sales forecasts can be achieved by incorporating its relationship with inventory and gross margin.

In conclusion, capturing the demand-stimulating effect of inventory is necessary for effective inventory management. However, it is not sufficient to achieve firm level success. Identifying the relationship between demand and inventory should be seen as a part of a broader action plan called demand-based (supply chain) management [55]. This approach seeks to maximize the total value (i.e., profits and/or other well-defined objectives of the entire supply chain) by addressing the interdependencies between inventory, demand, pricing, and marketing. Overlooking this approach and tackling the demand inventory relationship independently of pricing and marketing leads to suboptimal solutions. Put differently, pricing, promotional marketing, and/or other demand manipulation tools should be used to mitigate the negative consequences of the relationship between demand and inventory.

MODELS OF RETAIL COMPETITION

The actions of one retailer directly affect not only its own demand but also the demand faced by its competitors. Promotions, price discounts, and increases in service level can increase its demand due to customers switching their purchases from competitors to its stores. On the contrary, core service failures (e.g., stockouts, billing mistakes, and service catastrophes), service encounter failures (e.g., impolite and unknowledgeable employees), and pricing failures (e.g., high prices and deceptive pricing strategies) can lead to customer losses [56]. These changes in demand can be temporary or permanent. Therefore, a retailer should determine its operational policies taking into account their competitive implications.

Retail competition can be modeled in many ways of varying complexity depending on the extent of competitive interaction among firms in the marketplace. For example, we may consider

1. *single-period models*, in which consumers switch from one retailer to another in the immediate period upon experiencing a stockout;
2. *multiperiod models*, in which consumers switch from one retailer to another in a future period upon experiencing a stockout;
3. *models of full or partial information*, in which consumers have some prior knowledge of inventories at competing retailers and choose whether to visit a retailer upon evaluating their chances of finding a product in stock;
4. *learning models*, in which consumers do not have knowledge of product availability but learn about their probability of finding a product in stock based on their own historical experience with a retailer, and then modify their future shopping behavior accordingly;
5. *multidimensional models*, in which consumers select the retailer to visit based on many service dimensions, such as price, promotions, and service level.

At the simplest level (in (1) above), consider a model studied by Lippman and McCardle [57]. In this model, there are two retailers competing with each other in a single period. The price and cost parameters are given and are equal across retailers. The retailers compete only on the basis of their inventory levels y_i . The total demand is a random variable denoted as D . It is allocated between the retailers via some splitting rule; let D_i denote the initial allocation of demand to firm i . If the demand allocated to firm j is greater than its inventory, that is, if $D_j > y_j$, then a fraction a_i of the excess demand is reallocated to firm i . Thus, the effective demand at firm i , including its initial demand and reallocation, is given by $R_i = D_i + a_i \max\{0, D_j - y_j\}$, where $0 \leq a_i \leq 1$. Each retailer seeks to determine the inventory level that maximizes its expected profit. Note that each retailer's choice of inventory affects the demand faced by its competitor because of substitution or reallocation of excess demand.

Lippman and McCardle [57] describe many ways by which the initial demand for

each retailer may be obtained. For example, a deterministic splitting is one in which total demand is allocated between the retailers in a fixed proportion. A random splitting can be obtained in many ways: if each customer flips a coin to choose a retailer, then it is called an incremental random splitting of demand; if the first customer flips a coin to choose a retailer and each subsequent customer follows the previous customer, then it leads to a simple random splitting or herd behavior, that is, all of the demand is allocated to one or the other retailer with probability 0.5; finally, the initial demand at the two retailers may be given by independent random variables. Lippman and McCardle [57] present a beautiful example of a tourist bus visiting a chateau to illustrate the demand models. They show that there exists a pure strategy Nash equilibrium in inventory levels in this competitive game. The equilibrium need not be unique. Moreover, competition can be detrimental to the firms because it can drive down the industry profit to zero and drive up the total inventory level in the industry to be higher than the monopolist's optimal inventory, that is, the optimal inventory quantity if there were a single firm serving the entire demand.

Whereas single-period models allow us to study how competition affects the demand faced by a retailer in the current time period, multiperiod models (in (2) above) are useful to study the effect on demand in subsequent time periods. A multiperiod model of competition can allow us to measure the future goodwill cost of losing a customer if the service level in the current period is reduced. Following Hall and Porteus [58], suppose that there are two firms competing in a marketplace over a finite time horizon of T periods. Let D_{it} be the demand and y_{it} be the inventory level for firm i in period t . The unsatisfied demand is then given by $\max\{0, D_{it} - y_{it}\}$, and represents the number of customers who experience a stockout. Suppose that a fraction γ_i of these customers switch to the competitor in the next time period. Thus, if a firm were to increase its inventory, it would lose fewer customers to its competitor. The objective of the firm in the model is to determine its inventory

levels in order to maximize the total expected profits over the time horizon. With some additional simplifying assumptions, Hall and Porteus [58] show that this problem yields a unique subgame perfect Nash equilibrium. Their solution gives an imputed lost goodwill cost for each firm, which is a function of the present value of an additional customer in the next time period and the probability of losing that customer due to a stockout. The retailer with less sensitive customers, that is, a smaller value of γ_i , faces a lower imputed goodwill cost. Such a retailer will provide a lower service level but still enjoy less defections and a larger market share.

A different way to model competition due to inventory is to define fill rate or service level as a dimension of quality. Fill rate is defined as the fraction of demand satisfied by a retailer from stock. It is equal to the ratio of expected sales to mean demand; if y is the amount of inventory stocked by a retailer and D is the random demand faced by it with mean $E[D] = \mu$, then fill rate is equal to $E[\min\{D, y\}]/\mu$. The numerator in this expression is the expected sales of the firm, which is given by the minimum of demand and inventory. When the fill rate is high, fewer customers experience stockout, and therefore fewer customers are likely to be dissatisfied with the retailer. Therefore, the demand faced by a retailer becomes a function of its fill rate as well as the fill rates of its competitors. This concept is usually expressed in models of type (3)–(5) listed above by defining the market share of a retailer as

$$\frac{f_i}{\sum_j f_j},$$

where f_i is the service level offered by the subject retailer. In models of full information, customers know the inventory level stocked by each retailer and choose which firm to visit by weighing their probability of finding the product in stock [51]. In models of partial information, customers do not know the inventory levels of the retailers, and use other cues such as price to form expectations about the fill rates provided by retailers [51, 59]. Learning models are multiperiod models in which customers learn about the fill rates

from their past shopping experience at each firm [60,61].

Consumers' reaction to price and service quality variations might be asymmetric. That is, consumers might weigh negative experiences (losses) more than equivalent positive experiences (gains). For instance, Hardie *et al.* [62] argue that loss aversion and the position of brands relative to multiattribute reference points (e.g., price and quality) influence the brand choice. They empirically support this claim by estimating and comparing gain and loss coefficients for price, quality, loyalty, and the presence of advertising for orange juice sales using scanner data. These analyses can be utilized to model the effect of asymmetric consumer behavior on the new product introduction and price promotions. Similar asymmetry also arises in services based on satisfying and unsatisfying service experiences. For instance, consumers react more strongly to a stockout of a necessity items such as bread because they always expect to see such items in stock (negative bias). On the other hand, they might have positive bias for prestige products such as designer suits because they expect to search for these items. Gaur and Park [61] show that the effect of competition on total inventory levels and total industry profits depends on the type of bias exhibited by consumers. Moreover, when retailers have different costs, the difference in market shares of the retailers also depends on the type of bias. The lower cost retailer enjoys greater market share and profit differential when consumers have a negative bias, whereas a positive bias tends to attenuate the effect of competition for the higher cost retailer.

Competition does not necessarily occur in a single dimension. For instance, two retailers selling an identical product might compete on selling price and service. Service can be measured with a single proxy such as the fill rate [63] or it can be a performance measure which aggregates many aspects of the shopping experience such as promotions, advertising, and customer relations into a single decision variable [64]. In both cases, the product can be treated as a bundle of two attributes, price and service. Tsay and Agrawal [64] consider a single period setting

in which two competing retailers obtain a product from a common manufacturer, and discover that there are cases under which both retailers prefer an increase in competitive intensity because adding a small amount competition in one dimension mitigates the competitive intensity in the other. Bernstein and Federgruen [63] characterize an infinite-horizon, stochastic general equilibrium model for competing firms under different competition scenarios and demand processes.

Competition can affect firms in many other ways. A retailer might be willing to offer a monetary incentive to a customer in order to convince her to backorder instead of switching to another retailer [65]. The option to backorder reduces competition because unsatisfied demand is not necessarily lost. Another aspect of retail competition is the speed of delivery. If firms compete on the delivery time, then holding inventories is utilized as a tactic to reduce the customer waiting time and increase sales at the expense of high inventory holding costs. In fact, firms are more likely to switch from a make-to-order policy to a make-to-stock policy when the number of competitors increases. This type of competition increases consumer welfare and reduces retailers' profits [66]. Factors such as the firm and consumer characteristics, service quality, and searching costs also affect retail competition. For instance, McGahan and Ghemawat [67] study the relationship between firm sizes and competition to retain customers in a two stage game. In the first stage, firms try to build up loyalty among existing customers. In the second stage, they compete on price. Their analysis shows that large firms are likely to exhibit greater customer retention rates than their small rivals in equilibrium. Lastly, if customer search costs are low in an oligopolistic price competition setting, profit-maximizing firms may choose to have occasional stockouts to reduce competition. Reduced competition allows the firms to charge higher prices which might offset the effect of lost sales due to stockouts [68].

In conclusion, retailer competition has various aspects including, but not limited to, quantity, price, and service quality. Taking competition into account helps retailers

create more accurate models that can capture market dynamics and consumer choice, which will lead to more effective pricing and stocking decisions.

SUBSTITUTION AND TRANSSHIPMENT MODELS

Adoption of modern information technology tools such as ERP (enterprise resource planning) systems and web-based inventory tracking applications has led to remarkable improvements in retail supply chain transparency. Nowadays, it is possible to obtain real-time information regarding on-hand and in-transit inventory quantities for each location in a retailer's supply chain. In some systems, it is even possible to track lost sales due to shortages so that more accurate demand forecasts can be made. Reduced information and transportation costs and shorter transportation lead times have enabled companies to move items not only from an upper installation (e.g., a warehouse) to a lower installation (e.g., a store) but also between any two lateral points in the system (e.g., from one store to another) [69].

These technologic advancements have allowed companies to utilize two risk pooling techniques more effectively: product substitution and transshipment. Substitution redistributes demand from a stocked-out product to another product with excess inventory. Lateral transshipment redistributes inventory from stores with excess on-hand inventory to stores facing shortages or low inventory levels [70]. These techniques are complementary because substitution can be utilized when the consumer is willing to purchase a similar item instead of waiting for her favorite item to be restocked, whereas lateral transshipment is more appropriate when the consumer is willing to delay her purchase. For instance, a consumer might be willing to purchase a 13.5-oz shampoo of the same brand when she could not find the 25.4-oz size. However, she might be willing to wait for designer shoes if her size is temporarily out of stock. The mathematical models to compute solutions that provide substitution

and transshipment capabilities are similar. Below, we first summarize the effect of substitution on inventory management. Then, we describe transshipment policies. The topic of assortment planning is similar to substitution models and is discussed in a separate section. Typically, substitution models have a fixed number of available products, whereas the number of products to stock is a decision variable in assortment planning models.

Substitution

The implications of substitution on retail profits and inventory levels are important to study because consumers are often willing to purchase substitute items when they face stockouts. According to a survey conducted by Food Marketing Institute, more than 80% of the survey participants would be willing to buy a substitute item if their favorite item were not available [71]. Although demand substitution mitigates the effect of lost sales by switching demand from one item to another, it complicates inventory management because the sales of each item now depend not only on its own inventory and demand but also on the inventory and demand of all other items. Therefore, inventory policies developed without taking the substitution effect into account can lead to large profit losses.

There are two types of substitution phenomena, retailer driven and consumer driven. Under the first scenario, the retailer satisfies the demand for one product using another, possibly higher quality, product to mitigate stockouts. For instance, a downward substitution takes place when a high quality item can be downgraded and used as a substitute for a low quality item but not vice versa. Downward substitution can be understood using the model in Bassok *et al.* [71] as follows. Suppose that there are N products and N demand classes. The demand from class i can be satisfied using inventory of any product j such that $j \leq i$, thus representing downward substitution. The retailer earns revenue p_i for meeting demand of type i , incurs backorder cost π_i for shortages in class i , and incurs a cost of substitution b if demand for class i

is satisfied using inventory of some other product $j < i$. Product i can be purchased at cost c_i and its excess inventory can be salvaged at s_i . The retailer's profit maximization problem can be decomposed into two parts. In the first stage, the retailer determines the amount of inventory y_i of each product to stock. Then, a random amount of demand of each class is received. Given this demand, the retailer determines how to allocate the available inventory of various products among the demand classes in order to maximize its profit. The second stage problem can be formulated as the following linear program:

$$\begin{aligned} & G(y_1, \dots, y_N, D_1, \dots, D_N) \\ &= \max_{u_i, v_i, w_{ji}} \sum_{i=1}^N \left[p_i w_{ii} + \sum_{j=1}^{i-1} (p_j - b) w_{ji} \right. \\ & \quad \left. + s_i v_i - \pi_i u_i \right], \end{aligned}$$

subject to

$$\begin{aligned} u_i + \sum_{j=1}^i w_{ji} &= d_i \quad i = 1, \dots, N \\ v_i + \sum_{j=1}^N w_{ij} &= y_i \quad i = 1, \dots, N \\ w_{ij} &\geq 0 \quad i, j = 1, \dots, N \\ u_i, v_i &\geq 0 \quad i = 1, \dots, N. \end{aligned}$$

The decision variables in this formulation are w_{ij} , which is the amount of product i used to satisfy demand class j ; u_i , the amount of shortage in demand class i ; and v_i , the excess inventory of product i . The objective function consists of the revenue from meeting demand, the salvage value of excess inventory, and the cost of shortages. The constraints implement the balance of flow between supply and demand within the downward substitution structure. Given the solution of the second stage problem for any inventory level and demand realization, the first stage consists of determining the inventories to maximize

total expected profit, that is,

$$\max_{y_1, \dots, y_N} E[G(y_1, \dots, y_N, D_1, \dots, D_N)] - \sum_{i=1}^N c_i y_i.$$

Bassok *et al.* [72] derive a solution for this problem by showing that the profit function in the first stage problem is concave and submodular in inventory levels under mild assumptions on the price and cost parameters. Besides being suitable for many kinds of applications, this problem formulation has also been used to give an upper bound on the profit function of the substitution problem under consumer-driven substitution [73].

In consumer-driven substitution, the excess demand from one product is reallocated to other products according to some fixed substitution rule. We describe this model using Netessine and Rudi [74]. Consider the same notation as above. However, now, demand for class i must be satisfied first by available inventory of product i . Then, unsatisfied demand of class i is allocated to all the other products in a fixed proportion. Let a_{ij} denote the fraction of unsatisfied demand of class i allocated to product j , where $a_{ij} \in [0, 1]$ and $\sum_{j=1}^N a_{ij} \leq 1$. Therefore, the effective demand for product i is equal to

$$D_i + \sum_{j \neq i} a_{ji} (D_j - y_j)^+,$$

and the leftover inventory of product i is

$$\left(y_i - D_i - \sum_{j \neq i} a_{ji} (D_j - y_j)^+ \right)^+.$$

Here, $(D_j - y_j)^+$ denotes $\max\{0, D_j - y_j\}$. Thus, the retailer seeks to maximize its expected profit, which is a function of the total sales revenue, the salvage value of leftover inventory, and the purchasing cost of the inventory across all products. Note that the substitution is up to "first-level," that is, when excess demand of product i is reallocated to product j , then a stockout of product j does not lead to further reallocation of the leftover demand to other products. Even so, this problem is extremely difficult to solve. Netessine and Rudi [74] derive

first-order necessary optimality conditions for this problem, but show that there may be multiple local maxima. For simpler two- and three-product problems, the profit function is, however, concave [75,76].

Substantial savings in inventory-related costs can be achieved when items in the product portfolio are highly substitutable, that is, the probability of accepting another item is relatively high for a customer that cannot find her favorite item [77]. However, demand substitution does not necessarily lead to decrease in the total inventory level. For instance, for a two-product case, it has been shown that the total inventory level may increase when only one item is substitutable [78].

Transshipment

The purpose of transshipment is to redistribute inventory so that the right quantities are available in the right location [79]. Lateral transshipment can be divided into emergency lateral transshipment (ELT) and preventive lateral transshipment (PLT) [80]. ELT mandates emergency transfers from a retailer with excess stock to a retailer that has a stockout [81,82]. This policy responds to stockout incidents after the realization of demand. On the other hand, under a PLT policy, items are transferred among locations in order to balance inventories in anticipation of stockout [83]. PLT has a nonmyopic view which tries to reduce the risk of future stockouts by redistributing the inventory [70]. In both ELT and PLT policies, the initial inventory at each location is planned with the view to allowing transshipment in the future. In the most primitive case, if the retailer does not conduct any transshipment, the inventory decision for each location can be made independently. Thus, transshipment requires the inventories at all locations to be determined jointly, adding considerable complexity to the problem. The benefits are that it provides risk pooling across locations, and generally reduces the total inventory requirement.

Most of the early literature is concentrated on ELT policies for repairable items because they have low demand rates and high backorder costs and thus could benefit the most

from transshipment. The models used in this context are one-for-one continuous-review models similar to the seminal METRIC model of Sherbrooke [84]. For instance, Lee [81] studies a one-for-one multiechelon model for repairable items which allows lateral transshipments between identical retailers. He derives approximations for the commonly used performance measures such as the backorder levels and the number of lateral transshipments. These approximations are used to determine the optimal stocking levels. He shows that the use of lateral transshipment leads to large cost savings. Axsäter [82] extends these analyses under a scenario which the retailers are not identical. Archibald *et al.* [85] utilize Markov decision processes to study a two-location, multi-period, multi-item transshipment problem subject to capacity constraints. They show that the order-up-to policy is optimal when the demand for each item arises according to independent Poisson processes at each location. Although it is, in theory, possible to represent an inventory system as a Markov model and derive the steady-state probabilities, this approach may not always be computationally feasible since the state space grows exponentially with system size. Dada [86] focuses on developing a fast procedure to approximate the steady-state expected performance of a two-echelon system with transshipment. His model provides tight bounds on the system performance.

Due to the complexity of the transshipment problem, it is useful to devise simple heuristics. For instance, when shortage costs differ among locations, a simple yet effective technique is to allow unidirectional transshipments, that is, transshipments from locations with lower shortage cost to locations with higher shortage cost, but not in the opposite direction [87]. Another heuristic takes reorder points and batch quantities as given and tries to fulfill the excess demand at a retailer by a lateral transshipment from the retailer with most stock on hand [88]. This heuristic is useful under complex decision situations because it does not jointly optimize inventories across locations.

ELT policies for a supply chain with multiple retailers with different cost structures and demand parameters have also been studied under a continuous-review one-for-one inventory policy [89] as well as for a periodic-review system with a base stock inventory policy [90].

A PLT policy is modeled by Das [83] for a two-location stochastic inventory problem under centralized decision making. He implements this policy by setting a predetermined time point within each period at which the decision maker can move items from the overstocked location to the understocked location. He shows that a base stock policy with a transfer to the understocked location to bring its inventory level closest to its base stock level without decreasing the inventory level of the overstocked location below its base stock level is optimal.

Lee *et al.* [80] study a periodic-review model and develop a transshipment policy which can be classified as a combination of ELT and PLT. Namely, they define predetermined and fixed upper, lower, and target service levels which are used to compute the lateral transshipment quantities. At the end of each review period, retailers with inventory levels exceeding the corresponding upper service level send their excess inventories to retailers with low inventory levels or stockouts. A retailer with a low inventory level determines the amount of inventory that it can receive using the difference between the low and target service levels. Thus, this policy performs inventory balancing as well as emergency transshipments.

Two extreme transshipment policies are to never transship and always transship when there is a shortage at one location and stock is available at another location. It has been observed that choosing the better of these two extreme policies leads to a performance which is almost as good as a complex policy that takes the future impact of a stock transfer into account [91].

When a supply chain is centralized, the objective of transshipment is to optimize the overall system performance. However, when locations within a supply chain belong to

different organizations, transfer prices affect each location's profitability and willingness to participate in a transshipment activity. In general, when each location tries to maximize its own profits, the resulting Nash equilibrium will not maximize joint profits. However, it is possible to set transshipment prices to create supply chain coordination such that the decisions made by each location are consistent with joint-profit maximization [92]. Furthermore, in decentralized supply chains, it might be necessary to offer some incentives to supply chain partners in order to prevent free-riding and implement effective inventory distribution and transshipment policies [69]. Dong and Rudi [93] study a transshipment model in which an external supplier sells to multiple retail stores owned and operated by the same firm. They show that stores' order quantities are less sensitive to the wholesale price under a transshipment policy due to risk pooling. Hence, the manufacturer benefits from transshipments at the expense of the retailers because it can charge a higher wholesale price. Zhao *et al.* [94] consider a decentralized system with a large number of independent retailers and prove that a threshold requesting and rationing policy is optimal. Under this policy, there exist thresholds $Z_i \leq K_i \leq S_i$ for each retailer i , denoting the optimal requesting, rationing, and base stock levels, respectively, for retailer i . It is optimal to send a transshipment request to another retailer only if the inventory level is below the requesting level Z_i , and to fill a received transshipment request only if the inventory level is above the rationing level K_i .

To sum up, lateral transshipment is a way to perform risk pooling and satisfy demand especially for low demand, high stockout cost items. However, one should take the transshipment and replenishment lead times; related ordering, holding, transportation, and stockout costs; structure of the supply chain (e.g., centralized vs decentralized); alternative risk pooling techniques (e.g., substitution); and the underlying demand distributions into account in order to develop an effective transshipment policy. Chiu [95]

presents an extensive survey of the academic literature in this area.

CENTRAL PATH AND BARRIER ALGORITHMS FOR LINEAR OPTIMIZATION

KES ROOS

Faculty of Electrical Engineering,
Mathematics and Computer
Science, Delft University of
Technology, Delft,
The Netherlands

We consider the linear optimization (LO) problem in the standard form

$$\min \{c^T x : Ax = b, x \geq 0\},$$

with its dual problem

$$\max \{b^T y : A^T y + s = c, s \geq 0\}.$$

Here, $A \in \mathbf{R}^{m \times n}$, $b, y \in \mathbf{R}^m$, and $c, x, s \in \mathbf{R}^n$. Without loss of generality we assume that $\text{rank}(A) = m$. The vectors x, y , and s are the vectors of variables.

Our aim is to show how this primal–dual pair of LO problems can be solved in polynomial time by interior-point methods (IPMs). In most IPMs, the central path acts as a guideline to the set of optimal solutions. Assuming that a feasible solution is known that is close enough to the central path of a given LO problem, the problem can be solved by a simple numerical procedure that generates iterates on (or close to) the central path until we are close enough to the optimal set. In this way, one may find in polynomial time a solution with prescribed accuracy. One distinguishes between primal IPMs, dual IPMs, and primal–dual IPMs. Primal (dual) IPMs generate only primal (dual) feasible iterates, whereas primal–dual methods generate feasible iterates for both (P) and (D). In all cases, a crucial question concerns the availability of a starting point for the algorithm, that is, a feasible solution (close enough to the central path) of the given LO problem. If such a solution is at hand, the problem can be solved

with the just described method, which is then called a *feasible IPM*. In most cases, however, such a starting solution is not available. This certainly occurs if the given LO problem is infeasible or unbounded. In such cases, one may construct an artificial problem (see *Self-Dual Embedding Technique for Linear Optimization*) that can be solved by a feasible IPM and whose solution either informs us that the given LO problem is infeasible or unbounded, or it yields an optimal solution for the given problem. In this article, we leave out the issue of finding a starting point on the central path or close to it. Rather, we concentrate on the definition and main properties of the central path.

The theory underlying IPMs for LO has been developed in the last 25 years and is the result of the common effort of many researchers. In this article, we focus on elementary parts of this theory; nevertheless, trying to get a rather complete treatment of its main parts. Despite this, some topics could not be covered. For example, we do not touch the so-called *infeasible* IPMs; neither do we discuss sensitivity analysis based on the use of optimal partitions nor the so-called *potential reduction* IPMs and *target-following* methods. For these and related topics, we refer to the survey papers [1–3] and to some books devoted to IPMs [4–8].

We conclude this introduction with a simple lemma that will be used frequently in the sequel.

Lemma 1. *If x is feasible for (P) and (y, s) for (D) then $c^T x - b^T y = x^T s \geq 0$.*

Proof. Using the feasibility of x and (y, s) , we may write

$$\begin{aligned} c^T x - b^T y &= c^T x - (Ax)^T y = c^T x - x^T A^T y \\ &= c^T x - x^T (c - s) = x^T s. \end{aligned}$$

Since x and s are nonnegative, $x^T s \geq 0$. Hence the lemma follows.

This lemma implies the so-called *weak duality property*: If x is feasible for (P) and (y, s) for (D) then $c^T x \geq b^T y$. The difference $c^T x - b^T y$ is called the *duality gap* for the triple (x, y, s) .

NOTATIONS

The set of real numbers is denoted as $\mathbb{R}$. $\mathbb{R}^n$ and $\mathbb{R}_+^n$ denote the set of real vectors of length n and its subset of nonnegative vectors, respectively. The zero vector and all-one vector in $\mathbb{R}^n$ are denoted as 0_n and e_n , respectively; if this gives no rise to confusion we drop the subscript and simply write 0 or e . If f is a univariate function and $x \in \mathbb{R}^n$ then $f(x)$ is the vector with coordinates $f(x_i)$. This defines, for example, for any positive vector x the vectors x^2 , x^{-1} and $\sqrt{x}$. To any vector $x \in \mathbb{R}^n$, we associate the diagonal matrix X whose diagonal entries are the elements of x , in the same order. If also $s \in \mathbb{R}^n$, then Xs will be denoted in short as xs . So xs is the so-called Hadamard product: its entries are obtained by componentwise multiplication of x and s . Finally, if s is positive, then we denote xs^{-1} also as x/s .

PRIMAL METHOD

The main source of difficulties in solving the problem (P) is the presence of the inequality constraints $x \geq 0$. A basic idea in IPMs is to replace these inequalities by a barrier function and to reduce the solution of (P) to solving a sequence of minimization problems subject to the equality constraints $Ax = b$ only. For a detailed discussion of the history of this technique, we refer to the classic book of Fiacco and McCormick [9]. Nowadays it is commonly accepted that the logarithmic barrier function $-\sum_{i=1}^n \log x_i$ is very useful for our purpose. It was introduced in 1955 by Frisch [10]. Its domain is the interior of the nonnegative orthant, $\mathbb{R}_+^n$, and it reaches infinity if one approaches the boundary of $\mathbb{R}_+^n$. So, instead of (P), we consider the problem

$$\min \left\{ f_P(x; \mu) := \frac{c^T x}{\mu} - \sum_{i=1}^n \log x_i : Ax = b \right\}, \quad (\text{P}_\mu)$$

where μ may be any positive number. If μ approaches zero then the term containing $c^T x$ is given so much emphasis in the objective $f_P(x; \mu)$ that we may hope that the optimal solution of (P_μ) will provide a good approximation of an optimal solution of (P). We show below that the method works under the assumption that a strictly feasible solution x^0 , close to the minimizer of $f_P(x; \mu^0)$ for some $\mu^0 > 0$, is readily available. See the article titled **Self-Dual Embedding Technique for Linear Optimization** describes how to get into this situation.

Primal Newton Step

The working horse in all primal (and dual) IPMs is Newton's method for minimizing a convex function. Indeed, $f_P(x; \mu)$ is convex in x . One easily verifies this by computing the gradient and Hessian, which are as follows:

$$\nabla f_P(x; \mu) = \frac{c}{\mu} - x^{-1} \quad \text{and} \quad \nabla^2 f_P(x; \mu) = X^{-2}.$$

Since X is a positive diagonal matrix, it is positive definite, and so is X^{-2} , whence the convexity of $f_P(x; \mu)$ follows. The Newton step Δx at x is obtained by minimizing the second-order Taylor expansion of $f_P(x; \mu)$ subject to the constraint $A\Delta x = 0$:

$$\min \left\{ f_P(x; \mu) + \left(\frac{c}{\mu} - x^{-1} \right)^T \Delta x + \frac{1}{2} \Delta x^T X^{-2} \Delta x : A\Delta x = 0 \right\}.$$

Using a vector ξ as Lagrange multiplier, the first-order optimality conditions for this problem are

$$\begin{aligned} \frac{c}{\mu} - x^{-1} + X^{-2} \Delta x &= A^T \xi, \\ A\Delta x &= 0. \end{aligned}$$

Multiplying the first equation from the left with X and rearranging the terms give the equivalent system

$$\begin{aligned} e - \frac{Xc}{\mu} &= X^{-1} \Delta x - (AX)^T \xi, \\ AX \cdot X^{-1} \Delta x &= 0. \end{aligned}$$

The second equation shows that $X^{-1}\Delta x$ belongs to the null space of the matrix AX . Since $(AX)^T\xi$ belongs to the row space of AX , which is orthogonal to its null space, it follows that the first equation represents an orthogonal decomposition of the vector $e - \frac{Xc}{\mu}$ along the row space and the null space of AX . Denoting the orthogonal projection onto the null space of AX as P_{AX} implies that

$$X^{-1}\Delta x = P_{AX} \left(e - \frac{Xc}{\mu} \right). \quad (1)$$

An immediate consequence is that $X^{-1}\Delta x$ is the shortest vector in the 2-norm in the affine space containing $e - \frac{Xc}{\mu}$ and parallel to the row space of AX . The vectors in this affine space have the form

$$\begin{aligned} e - \frac{Xc}{\mu} + (AX)^T\xi &= e - \frac{X(c - A^T(\mu\xi))}{\mu}, \quad \xi \in \mathbb{R}^m \\ &= e - \frac{X(c - A^Ty)}{\mu}, \quad y \in \mathbb{R}^m. \end{aligned}$$

Now let $y(x, \mu)$ denote the vector y that minimizes the 2-norm of the last expression, and $s(x, \mu) = c - A^Ty(x, \mu)$. In other words, with $\|\cdot\|$ denoting the 2-norm,

$$s(x, \mu) := \operatorname{argmin}_s \left\{ \left\| e - \frac{Xs}{\mu} \right\| : A^Ty + s = c \right\}. \quad (2)$$

Then it follows that the Newton direction satisfies

$$X^{-1}\Delta x = e - \frac{Xs(x, \mu)}{\mu}. \quad (3)$$

This characterization of the Newton direction turns out to be extremely useful, as it will become clear in the analysis below.

Primal Proximity Measure and Quadratic Convergence

For the moment we assume that $f_P(x; \mu)$ has a minimizer, which we denote as $x(\mu)$. To measure progress of the Newton process, we need a measure for the distance of x to $x(\mu)$. Owing to the convexity of $f_P(x; \mu)$, x is a minimizer if and only if the Newton step at x equals the zero vector. A natural candidate

for measuring proximity to $x(\mu)$ is therefore the norm of the Newton step Δx . Instead, before taking the norm, we scale Δx to $X^{-1}\Delta x$, and define

$$\delta(x, \mu) := \|X^{-1}\Delta x\| = \left\| e - \frac{Xs(x, \mu)}{\mu} \right\|, \quad (4)$$

where the last equality is due to Equation (3). Note that $\delta(x, \mu) = 0$ if $x = x(\mu)$, because then $\Delta x = 0$, and otherwise $\delta(x, \mu) > 0$. The point that results by taking a (full) Newton step at x is denoted as x^+ . According to Equation (3), we may write

$$\begin{aligned} x^+ &= x + \Delta x = x + X \left(e - \frac{Xs(x, \mu)}{\mu} \right) \\ &= X \left(2e - \frac{Xs(x, \mu)}{\mu} \right). \end{aligned} \quad (5)$$

Using this we can show that the Newton process is quadratically convergent in terms of the proximity measure $\delta(x, \mu)$, provided that x is close enough to $x(\mu)$.

Lemma 2. *If $\delta(x, \mu) < 1$ then x^+ is a strictly feasible solution of (P). Moreover, $\delta(x^+, \mu) \leq \delta(x, \mu)^2$.*

Proof. It will be convenient to introduce the vector w as follows:

$$w := \frac{Xs(x, \mu)}{\mu}. \quad (6)$$

Then we have $\delta(x, \mu) = \|e - w\|$. Hence, $\delta(x, \mu) < 1$ implies that $\|e - w\| < 1$. Therefore, $0 < w_i < 2$, for each i , which implies that $2e - w > 0$. Using Equation (5), we get $x^+ = X(2e - w) > 0$, proving that x^+ is positive. The relation $Ax^+ = b$ also holds, because $Ax = b$ and $A\Delta x = 0$. This proves the first statement in the theorem.

The definition of $s(x^+, \mu)$ implies the following:

$$\begin{aligned} \delta(x^+, \mu) &= \left\| e - \frac{Xs(x^+, \mu)}{\mu} \right\| \leq \left\| e - \frac{Xs(x, \mu)}{\mu} \right\| \\ &= \|e - X^{-1}X^{-1}w\|. \end{aligned}$$

Using once more that $x^+ = X(2e - w)$ we find

$$\begin{aligned} e - X + X^{-1}w &= e - X(2I - W)X^{-1}w \\ &= e - (2I - W)w \\ &= e - 2w + Ww = (e - w)^2. \end{aligned}$$

In this chain of equalities, we used the fact that diagonal matrices commute. We also recall that, according to our convention, $(e - w)^2$ denotes the Hadamard product of $(e - w)$ with itself. Substituting this we obtain

$$\delta(x^+, \mu)^2 = \|(e - w)^2\|^2 \leq \|w - e\|^4 = \delta(x, \mu)^4,$$

where we used that $\|z^2\| \leq \|z\|^2$, for any $z \in \mathbb{R}^n$. Hence, it follows that $\delta(x^+, \mu) \leq \delta(x, \mu)^2$, which was to be shown.

The importance of Lemma 2 is clear: if we repeat doing Newton steps, the proximity measure converges quadratically fast to zero, which implies that the iterates converge to $x(\mu)$. As a corollary we may state the following.

Corollary 1. *If $\delta(x, \mu) < 1$ for some (strictly feasible) x then $f_P(x; \mu)$ has a minimizer.*

Proof. If we repeat doing Newton steps, then the values of $\delta(x, \mu)$ converge (quadratically fast) to zero. The limit point $\bar{x}$ satisfies $\delta(\bar{x}, \mu) = 0$, which implies that the Newton step $\Delta\bar{x}$ at $\bar{x}$ vanishes; this means that $\bar{x}$ is a minimizer of $f_P(x, \mu)$.

Updating the Barrier Parameter

Using Corollary 1, we show in this section that if $f_P(x; \mu)$ has a minimizer for some positive μ then $f_P(x; \mu)$ has a minimizer for every positive μ . For this we need the following lemma. Note that in this lemma, we allow θ to be negative.

Lemma 3. *Let $\theta < 1$ and $\mu^+ = (1 - \theta)\mu$. Then*

$$\delta(x, \mu^+) \leq \frac{\delta(x, \mu) + |\theta|\sqrt{n}}{1 - \theta}.$$

Proof. With w , as defined in Equation (6), the definition of $s(x, \mu)$ implies the following:

$$\begin{aligned} \delta(x, \mu^+) &= \left\| e - \frac{Xs(x, \mu^+)}{\mu^+} \right\| \leq \left\| e - \frac{Xs(x, \mu)}{\mu^+} \right\| \\ &= \left\| e - \frac{w}{1 - \theta} \right\| = \frac{\|(e - w) - \theta e\|}{1 - \theta}. \end{aligned}$$

Since $\|e - w\| = \delta(x, \mu)$ and $\|\theta e\| = |\theta|\sqrt{n}$, the lemma follows by applying the triangle inequality.

Corollary 2. *If $\delta(x, \mu) < 1$ for some (strictly feasible) x and some $\mu > 0$, then $f_P(x; \mu)$ has a minimizer for every $\mu > 0$.*

Proof. Suppose $\delta(x, \mu^0) < 1$ for some $\mu^0 > 0$. Then, by Corollary 1, $f_P(x; \mu^0)$ has a minimizer. We express this by saying that $x(\mu^0)$ exists. Taking $x = x(\mu^0)$, we then have $\delta(x, \mu^0) = 0$. Using Lemma 3 one easily deduces from this that $\delta(x, \mu) < 1$ whenever

$$\frac{\sqrt{n}}{\sqrt{n} + 1} \mu^0 < \mu < \frac{\sqrt{n}}{\sqrt{n} - 1} \mu^0. \quad (7)$$

Using Corollary 1 again, we conclude that $x(\mu)$ exists for any such μ . Thus, we see that whenever $x(\mu)$ exists for some $\mu = \mu^0 > 0$ then $x(\mu)$ also exists for all μ in the open interval around μ^0 as given by Equation (7). By applying the same argument to the points in this interval one easily understands that $x(\mu)$ exists for all μ satisfying

$$\left(\frac{\sqrt{n}}{\sqrt{n} + 1} \right)^2 \mu^0 < \mu < \left(\frac{\sqrt{n}}{\sqrt{n} - 1} \right)^2 \mu^0.$$

By repeating this argument k times, we get that $x(\mu)$ exists for all μ satisfying

$$\left(\frac{\sqrt{n}}{\sqrt{n} + 1} \right)^k \mu^0 < \mu < \left(\frac{\sqrt{n}}{\sqrt{n} - 1} \right)^k \mu^0.$$

By taking k large enough we can reach every positive value of μ , and hence the corollary follows.

Central Path

We are now in a position to define the central path of (P). Assuming again that $\delta(x, \mu) < 1$ for some (strictly feasible) x and some $\mu > 0$, we have shown that $f_P(x; \mu)$ has a minimizer, denoted as $x(\mu)$, for every positive μ . If μ runs through all positive real numbers, then $x(\mu)$ runs through a curve in the interior of the feasible region of (P). This curve is called the *central path* of (P). Below we show that if μ approaches zero, then the central path converges to an optimal solution of (P). As a consequence, if (P) has a unique optimal solution, which then is a vertex of the feasible region, then the central path converges to this vertex. If, however, there are more optimal solutions, then the limit of the central path is a specific optimal solution, called the *analytic center* of the optimal set, which is a strictly complementary solution, certainly not a vertex. This reveals a remarkable difference with the simplex method, which always generates a vertex solution.

In this section, we discuss some important properties of the central path. We start with an enlightening characterization of the points on the central path. As we discussed earlier, due to the convexity of $f_P(x; \mu)$, x is a minimizer if and only if the Newton step equals the zero vector. Because of Equations (2) and (3) this happens if and only if $e - \frac{xs(x, \mu)}{\mu} = 0$, or, equivalently, $xs(x, \mu) = \mu e$. We conclude that x minimizes $f_P(x; \mu)$ if and only if there exist y and s such that

$$Ax = b, x \geq 0, \quad (8)$$

$$A^T y + s = c, s \geq 0, \quad (9)$$

$$xs = \mu e. \quad (10)$$

Note that Equation (8) is the condition for primal feasibility and Equation (9) is the condition for dual feasibility. Condition (10) is called the *centering condition*. Since the system (Eqs 8–10) represents the first-order optimality conditions for a minimizer of $f_P(x; \mu)$; it therefore is also known as the *Karush–Kuhn–Tucker* (KKT) system for (P).

Now let the triple (x, y, s) solve this system (for some fixed $\mu > 0$). Since $f_P(x; \mu)$ has a unique minimizer, x is the unique solution of the system (Eqs 8–10). But, in view of

centering condition (10) s is also unique, so is y because of Equation (9) and because A has full row rank. This shows that the KKT system has a unique solution, for every $\mu > 0$. This solution is denoted as $(x(\mu), y(\mu), s(\mu))$, while $x(\mu)$ is called the μ center of (P), and $(y(\mu), s(\mu))$ the μ center of (D). Indeed, as will become clear in the section titled “Dual Method”, the dual problem also has a central path, and it consists of the pairs $(y(\mu), s(\mu))$, with $\mu > 0$.

We conclude this section with four important remarks. First, in see the article titled ***Self-Dual Embedding Technique for Linear Optimization*** it is shown that every primal–dual pair of problems (P) and (D) can be embedded in a (self-dual) artificial problem for which a solution of Equations (8)–(10) is at hand with $\mu = 1$. This means that the artificial problem has a central path. The importance of this artificial problem is that the information at the limit of its central path can be used to solve (P) and (D).

The second remark concerns the condition that we used so far to guarantee the existence of the central path of (P): the assumption that $\delta(x, \mu) < 1$ for some (strictly feasible) x and some $\mu > 0$. This condition can be weakened considerably, however. Note that the centering condition implies that $x(\mu) > 0$ and $s(\mu) > 0$ for every $\mu > 0$. This means that the central path can exist only if (P) has a strictly feasible solution x , that is, satisfying $Ax = b, x > 0$ and (D) has a strictly feasible solution (y, s) , that is, satisfying $A^T y + s = c, s > 0$. We want to point out that the converse is also true: if both (P) and (D) have a strictly feasible (or interior) solution, then the central path exists. In this presentation we do not need this fact, for its proof we refer to Refs 5–8. As a consequence, we may state that the central path exists if and only if both (P) and (D) have a strictly feasible solution. We refer to this condition as the *interior-point condition* (IPC).

Third, we want to emphasize the surprising fact that one may associate a dual feasible solution (y, s) to any primal feasible solution x on (or close to) the central path. This is now obvious if x is on the central path, say $x = x(\mu)$, because then we may take $y = y(\mu)$ and $s = s(\mu)$. The duality gap for

these solutions can be obtained from Lemma 1 and the centering equation

$$\begin{aligned} c^T x(\mu) - b^T y(\mu) &= x(\mu)^T s(\mu) = e^T(x(\mu)s(\mu)) \\ &= e^T(\mu e) = n\mu. \end{aligned} \quad (11)$$

The following lemma generalizes this result to the case where x is close to the μ center $x(\mu)$.

Lemma 4. *If $\delta(x, \mu) \leq 1$, then the pair $(y(x, \mu), s(x, \mu))$ is dual feasible. Moreover,*

$$\begin{aligned} \mu(n - \delta(x, \mu)\sqrt{n}) &\leq c^T x - b^T y(x, \mu) \\ &\leq \mu(n + \delta(x, \mu)\sqrt{n}). \end{aligned}$$

Proof. As noted earlier, if w is defined by Equation (6), then $\delta(x, \mu) = \|e - w\|$. As it was pointed out earlier, $\delta(x, \mu) \leq 1$ implies that w is nonnegative. Hence, $Xs(x, \mu)$ is nonnegative. Since X is a positive diagonal matrix, it follows that $s(x, \mu) \geq 0$, proving the first statement in the lemma. Owing to Lemma 1, we therefore may write

$$c^T x - b^T y(x, \mu) = x^T s(x, \mu).$$

Furthermore, application of the Cauchy–Schwarz inequality gives

$$\begin{aligned} \delta(x, \mu)\sqrt{n} &= \left\| e - \frac{Xs(x, \mu)}{\mu} \right\| \|e\| \\ &\geq \left| e^T \left(e - \frac{Xs(x, \mu)}{\mu} \right) \right| \\ &= \left| n - \frac{x^T s(x, \mu)}{\mu} \right|. \end{aligned}$$

From this we derive

$$-\delta(x, \mu)\sqrt{n} \leq n - \frac{x^T s(x, \mu)}{\mu} \leq \delta(x, \mu)\sqrt{n},$$

which implies the inequalities in the lemma.

Fourth, and last, along the primal central path the primal objective value is monotonically increasing with respect to μ . This can be understood easily. Letting

$0 < \mu_1 \leq \mu_2$ and $x^1 = x(\mu_1)$ and $x^2 = x(\mu_2)$, we claim that $c^T x^1 \leq c^T x^2$. Since x^1 minimizes $f_P(x; \mu_1)$, we have $f_P(x^1; \mu_1) \leq f_P(x^2; \mu_1)$. For a similar reason, $f_P(x^2; \mu_2) \leq f_P(x^1; \mu_2)$. In other words,

$$\begin{aligned} \frac{c^T x^1}{\mu_1} - \sum_{i=1}^n \log x_i^1 &\leq \frac{c^T x^2}{\mu_1} - \sum_{i=1}^n \log x_i^2, \\ \frac{c^T x^2}{\mu_2} - \sum_{i=1}^n \log x_i^2 &\leq \frac{c^T x^1}{\mu_2} - \sum_{i=1}^n \log x_i^1. \end{aligned}$$

The sums in these inequalities can be eliminated by adding the above inequalities, which gives

$$\frac{c^T x^1}{\mu_1} + \frac{c^T x^2}{\mu_2} \leq \frac{c^T x^2}{\mu_1} + \frac{c^T x^1}{\mu_2},$$

which is equivalent to

$$\left(\frac{1}{\mu_1} - \frac{1}{\mu_2} \right) (c^T x^1 - c^T x^2) \leq 0.$$

Since $\frac{1}{\mu_1} - \frac{1}{\mu_2} > 0$, we obtain $c^T x^1 \leq c^T x^2$, proving the claim. A similar result holds for the dual central path: the dual objective value is monotonically decreasing with respect to μ . The proof is easy and similar to the previous case. We shall dispense with it because it involves the dual logarithmic barrier function that is introduced in the section titled “Dual Methods”. Since $c^T x(\mu) - b^T y(\mu) = n\mu$, from Equation (11), it follows that if μ approaches zero then $c^T x(\mu)$ and $b^T y(\mu)$ converge to the same value, which is the common optimal objective value of (P) and (D).

Primal Interior-Point Method

The following lemma provides a numerical method to follow the primal central path (approximately).

Lemma 5. *Let $\delta(x, \mu) \leq \frac{1}{2}$. If $\theta = \frac{1}{6\sqrt{n}}$ and x^+ and μ^+ are as defined before, then $\delta(x^+, \mu^+) \leq \frac{1}{2}$.*

Proof. Using Lemmas 2 and 3, successively we may write

$$\delta(x^+, \mu^+) \leq \frac{\delta(x^+, \mu) + \theta\sqrt{n}}{1 - \theta} \leq \frac{\delta(x, \mu)^2 + \theta\sqrt{n}}{1 - \theta}.$$

Since $\delta(x, \mu) \leq \frac{1}{2}$ and $\theta\sqrt{n} = \frac{1}{6}$, it follows that

$$\delta(x^+, \mu^+) \leq \frac{\frac{1}{4} + \frac{1}{6}}{\frac{5}{6}} = \frac{1}{2},$$

proving the lemma.

The above lemma makes clear that by repeatedly performing the Newton step and a barrier update with $\theta = \frac{1}{6\sqrt{n}}$, we can get as close to the optimal set as we wish. A more precise formulation of the algorithm is as follows:

Algorithm 1. A full-Newton step primal IPM for LO

Input:

(x^0, μ^0) , with x strictly feasible, $\mu^0 > 0$, and $\delta(x^0, \mu^0) \leq \frac{1}{2}$;
accuracy parameter $\varepsilon > 0$;
barrier update parameter θ , $0 < \theta < 1$;

begin

$x := x^0; \mu := \mu^0$.

while $n\mu > \varepsilon$

$x := x + \Delta x$;

$\mu := (1 - \theta)\mu$.

endwhile

end

Theorem 1. Taking $\theta = \frac{1}{6\sqrt{n}}$, the algorithm requires no more than

$$6\sqrt{n} \log \frac{n\mu^0}{\varepsilon}$$

iterations. The last generated point x is strictly feasible, whereas $y(x, \mu)$ is dual feasible. Moreover, $c^T x - b^T y(x, \mu) \leq \frac{3}{2}\varepsilon$.

Proof. By Lemma 5, after each iteration of the algorithm, the vector x will be strictly feasible and $\delta(x, \mu) \leq \frac{1}{2}$. After the k th iteration, we have $\mu = (1 - \theta)^k \mu^0$. Hence, the algorithm must have stopped if k is such that $(1 - \theta)^k n\mu^0 \leq \varepsilon$. By taking logarithms on both sides, the inequality reduces to

$$-k \log(1 - \theta) \geq \log \frac{n\mu^0}{\varepsilon}.$$

Since $-\log(1 - \theta) > \theta$, this will certainly hold if $k\theta \geq \log \frac{n\mu^0}{\varepsilon}$. Substituting the value of θ , we find the iteration bound in the theorem.

Now let x be the last generated point and μ the final value of the barrier parameter.

Then $n\mu \leq \varepsilon$. From Lemma 4, we obtain that $y(x, \mu)$ is dual feasible. Finally, using $n \geq 1$, we may write

$$\begin{aligned} c^T x - b^T y(x, \mu) &\leq \mu(n + \delta(x, \mu)\sqrt{n}) \\ &\leq \frac{\varepsilon}{n}(n + \delta(x, \mu)\sqrt{n}) \\ &= \varepsilon \left(1 + \frac{\delta(x, \mu)}{\sqrt{n}} \right) \leq \frac{3}{2}\varepsilon. \end{aligned}$$

This completes the proof.

DUAL METHOD

It will be no surprise that we can apply a similar approach to solve the dual problem as described for the primal problem in the previous section. In this section, we briefly describe how this can be worked out, without going into too much detail.

First we eliminate the nonnegativity constraint $s \geq 0$ by using the logarithmic barrier function $-\sum_{i=1}^n \log s_i$. So, to solve (D), we

consider the auxiliary problem

$$\max \left\{ f_D(y; \mu) := \frac{b^T y}{\mu} + \sum_{i=1}^n \log s_i : A^T y + s = c \right\}, \quad (D_\mu)$$

where μ may be any positive number. Since A has full row rank, we feel free to represent a dual feasible pair (y, s) by either y or s , because either of these uniquely determines the other.

The gradient and Hessian, with respect to y , are as follows:

$$\nabla_y f_D(y; \mu) = \frac{b}{\mu} - A s^{-1}$$

and

$$\nabla_y^2 f_D(y; \mu) = A S^{-2} A^T,$$

where s^{-1} denotes the vector whose entries are s_i^{-1} and $S = \text{diag}(s)$. Hence, the Newton step is given as

$$\begin{aligned} \Delta y &= (A S^{-2} A^T)^{-1} \left(\frac{b}{\mu} - A s^{-1} \right), \\ \Delta s &= -A^T \Delta y. \end{aligned}$$

Let $\bar{x}$ be such that $A\bar{x} = b$. Then, we may write

$$\begin{aligned} S^{-1} \Delta s &= -S^{-1} A^T (A S^{-2} A^T)^{-1} \left(\frac{A\bar{x}}{\mu} - A s^{-1} \right) \\ &= -S^{-1} A^T (A S^{-2} A^T)^{-1} A S^{-1} \left(\frac{S\bar{x}}{\mu} - e \right). \end{aligned}$$

At this stage we recognize $S^{-1} A^T (A S^{-2} A^T)^{-1} A S^{-1}$ as the matrix of the orthogonal projection onto the row space of $A S^{-1}$. Denoting this matrix as $P_{A S^{-1}}^\perp$, we thus have

$$S^{-1} \Delta s = P_{A S^{-1}}^\perp \left(e - \frac{S\bar{x}}{\mu} \right). \quad (12)$$

Defining

$$x(s, \mu) := \operatorname{argmin}_x \left\{ \left\| e - \frac{Sx}{\mu} \right\| : Ax = b \right\}, \quad (13)$$

one easily understands, just using the same arguments as in the primal case, that

$$S^{-1} \Delta s = e - \frac{Sx(s, \mu)}{\mu}. \quad (14)$$

The point that results by taking a (full) Newton step at s is denoted as s^+ . According to Equation (14), we may write

$$\begin{aligned} s^+ &= s + \Delta s = s + S \left(e - \frac{Sx(s, \mu)}{\mu} \right) \\ &= S \left(2e - \frac{Sx(s, \mu)}{\mu} \right). \end{aligned} \quad (15)$$

As proximity measure, we use

$$\delta(y, \mu) := \|S^{-1} \Delta s\| = \left\| e - \frac{Sx(s, \mu)}{\mu} \right\|. \quad (16)$$

We can now state the following results, whose proofs are omitted since they are completely similar to the proofs of the corresponding results for the primal case.

Lemma 6. *If $\delta(y, \mu) < 1$, then $y^+ := y + \Delta y$ is a strictly feasible solution of (D). Moreover, $\delta(y^+, \mu) \leq \delta(y, \mu)^2$.*

Corollary 3. *If $\delta(y, \mu) < 1$ for some (strictly feasible) y , then $f_D(y; \mu)$ has a maximizer.*

Lemma 7. *Let $\theta < 1$ and $\mu^+ = (1 - \theta)\mu$. Then*

$$\delta(y, \mu^+) \leq \frac{\delta(y, \mu) + |\theta| \sqrt{n}}{1 - \theta}.$$

Corollary 4. *If $\delta(y, \mu) < 1$ for some (strictly feasible) y and some $\mu > 0$, then $f_D(x; \mu)$ has a maximizer for every $\mu > 0$.*

On the basis of these results we may conclude that just as in the primal case, the (unique) maximizer of $f_D(y; \mu)$ is the pair $(y(\mu), s(\mu))$ which is determined by the system (8)–(10).

Lemma 8. *If $\delta(y, \mu) \leq 1$, then $x(s, \mu)$ is primal feasible. Moreover,*

$$\begin{aligned}\mu(n - \delta(x, \mu)\sqrt{n}) &\leq c^T x(s, \mu) - b^T y \\ &\leq \mu(n + \delta(x, \mu)\sqrt{n}).\end{aligned}$$

Lemma 9. *Let $\delta(y, \mu) \leq \frac{1}{2}$. If $\theta = \frac{1}{6\sqrt{n}}$ and (y^+, s^+) and μ^+ are as defined before, then $\delta(y^+, \mu^+) \leq \frac{1}{2}$.*

Owing to these results, the dual algorithm is quite similar to the primal algorithm (Algorithm 1.5), as shown below.

Algorithm 2. A full-Newton step dual IPM for LO

Input:

(y^0, s^0, μ^0) , with (y^0, s^0) strictly feasible, $\mu^0 > 0$, and $\delta(y^0, \mu^0) \leq \frac{1}{2}$;
accuracy parameter $\varepsilon > 0$;
barrier update parameter θ , $0 < \theta < 1$;

begin

$y := y^0; s := s^0; \mu := \mu^0$.

while $n\mu > \varepsilon$

$(y, s) := (y, s) + (\Delta y, \Delta s)$;

$\mu := (1 - \theta)\mu$.

endwhile

end

PRIMAL–DUAL METHOD

The primal and dual IPMs discussed so far are very much in the spirit of the barrier methods that received much attention in the 1970s. At that time much emphasis was given to proving convergence of such methods. Only after the work of Karmarkar it became clear (in the late 1980s) that by a proper setting of the parameters in the algorithm we can not only prove convergence but also obtain polynomial iteration bounds [11]. More importantly, a new class of methods was developed that take much more profit of the duality properties in LO. As we know, every LO problem has a dual problem. We also have seen, more or less to our surprise, that when solving an LO problem with a primal (or dual) IPM, the output of the algorithm is not only a primal optimal solution (with prescribed accuracy) but also a dual optimal solution (with the same accuracy). Note that this phenomenon also occurs when solving an LO problem with the simplex method. It has turned out, however, that IPMs can

Theorem 2. *Taking $\theta = \frac{1}{6\sqrt{n}}$, the algorithm requires no more than*

$$6\sqrt{n} \log \frac{n\mu^0}{\varepsilon}$$

iterations. The last generated pair (y, s) is strictly feasible, whereas $x(s, \mu)$ is primal feasible. Moreover, $c^T x(s, \mu) - b^T y \leq \frac{3}{2}\varepsilon$.

profit much more from the inherent duality in LO; namely, by designing methods that generate iterates both in the primal space and the dual space. These are the so-called primal–dual methods that we discuss in this section.

Primal–Dual Search Direction

Primal–dual methods heavily rely upon the KKT system (Eqs 8–10). Suppose we have a strictly feasible triple (x, y, s) —that is, x is strictly feasible for (P) and (y, s) strictly feasible for (D)—and that we want to find the μ centers of (P) and (D), where μ is an arbitrary positive number. Denoting $\Delta x = x(\mu) - x$, $\Delta y = y(\mu) - y$, and $\Delta s = s(\mu) - s$, this means that we are looking for a triple $(\Delta x, \Delta y, \Delta s)$ such that

$$A\Delta x = 0,$$

$$A^T \Delta y + \Delta s = 0,$$

$$(x + \Delta x)(s + \Delta s) = \mu e.$$

Unfortunately the third equation is nonlinear in the unknown vectors Δx and Δs , because of the quadratic term $\Delta x \Delta s$ in

$$(x + \Delta x)(s + \Delta s) = xs + x\Delta s + s\Delta x + \Delta x \Delta s.$$

At this stage we use a fundamental idea (which is again due to Newton) for solving nonlinear equation systems, namely, to ignore the nonlinear term. This leads to the following linear system of equations in the search directions Δx , Δy , and Δs :

$$A\Delta x = 0, \quad (17)$$

$$A^T \Delta y + \Delta s = 0, \quad (18)$$

$$x\Delta s + s\Delta x = \mu e - xs. \quad (19)$$

Lemma 10. *The system (Eqs 17–19) has a unique solution.*

Proof. The proof can be given in several ways. Our proof is based on a rescaling scheme that is also useful in the analysis of the algorithm that we present later. It uses the vector v defined by

$$v := \sqrt{\frac{xs}{\mu}}. \quad (20)$$

Obviously v equals the all-one vector if and only if $xs = \mu e$. In other words, $v = e$ holds if and only if $x = x(\mu)$ and $s = s(\mu)$. Using v , we define scaled versions $\dot{x}$ and $\dot{s}$ of the search directions Δx and Δs , respectively, according to

$$\dot{x} = \frac{v\Delta x}{x} \quad \text{and} \quad \dot{s} = \frac{v\Delta s}{s}. \quad (21)$$

In other words, with $V = \text{diag}(v)$, one has $\Delta x = V^{-1}X\dot{x}$ and $\Delta s = V^{-1}S\dot{s}$. Therefore, we may rewrite the system (Eqs 17–19) as follows:

$$\begin{aligned} AV^{-1}X\dot{x} &= 0, \\ A^T \Delta y + V^{-1}S\dot{s} &= 0, \\ xv^{-1}s\dot{s} + sv^{-1}x\dot{x} &= \mu e - xs. \end{aligned}$$

Since $xs = \mu v^2$, the third equation simplifies to $\mu v(\dot{x} + \dot{s}) = \mu(e - v^2)$, which is equivalent to $\dot{x} + \dot{s} = v^{-1} - v$. On the other hand, defining

$$d = \sqrt{\frac{x}{s}},$$

we have $V^{-1}X = \sqrt{\mu}D$ and $V^{-1}S = \sqrt{\mu}D^{-1}$, where $D = \text{diag}(d)$. So, the first equation is equivalent to $AD\dot{x} = 0$ and the second equation to $A^T \Delta y + \sqrt{\mu}D^{-1}\dot{s} = 0$, which can be rewritten as $(AD)^T \frac{\Delta y}{\sqrt{\mu}} + \dot{s} = 0$. Thus, with $\bar{A} = AD$, we obtain that

$$\bar{A}\dot{x} = 0, \quad (22)$$

$$\bar{A}^T \frac{\Delta y}{\sqrt{\mu}} + \dot{s} = 0, \quad (23)$$

$$\dot{x} + \dot{s} = v^{-1} - v. \quad (24)$$

From the first two equations we conclude that $\dot{x}$ belongs to the null space of $\bar{A}$ and $\dot{s}$ to the row space of $\bar{A}$. Hence, we derive from the third equation that $\dot{x}$ and $\dot{s}$ are the components of $v^{-1} - v$ in these two (orthogonal) spaces. Thus, we obtain that

$$\dot{x} = P_{\bar{A}}(v^{-1} - v) \quad \text{and} \quad \dot{s} = P_{\bar{A}}^\perp(v^{-1} - v), \quad (25)$$

where $P_{\bar{A}}$ denotes the orthogonal projection onto the null space of $\bar{A}$, and $P_{\bar{A}}^\perp$ the orthogonal projection onto orthogonal complement of the null space of $\bar{A}$, which is the row space of $\bar{A}$. This proves that $\dot{x}$ and $\dot{s}$ are unique. Since A has full row rank, so does $\bar{A}$. Therefore, it follows from Equation (23) that Δy is also unique. Hence, the lemma has been proved.

The search directions defined by Equations (17)–(19) are used in all primal–dual IPMs. Because of Equation (21) we may rewrite Equation (25) as follows:

$$\begin{aligned} \Delta x &= V^{-1}XP_{AD}(v^{-1} - v), \\ \Delta s &= V^{-1}SP_{AD}^\perp(v^{-1} - v). \end{aligned}$$

A natural question is how these directions compare with the primal and dual directions that we have seen before, as given

by Equations (1) and (12). Obviously, if $v = e$, that is, if the triple (x, y, s) consists of the μ centers of (P) and (D), then all directions vanish, and therefore are equal, but in general the directions will be different.

We denote the result of a (full) Newton step at the triple (x, y, s) as (x^+, y^+, s^+) . So, we have

$$\begin{aligned} x^+ &= x + \Delta x, \\ y^+ &= y + \Delta y, \\ s^+ &= s + \Delta s. \end{aligned}$$

Since we omitted the quadratic term in the definition of the Newton directions, (x^+, y^+, s^+) will in general not coincide with the triple of μ centers. But, as it is shown in the next section, if (x, y, s) is close enough to $(x(\mu), y(\mu), s(\mu))$ then (x^+, y^+, s^+) will be significantly closer. For the moment we establish a related, but weaker, result, namely, that after a Newton step the duality gap is equal to the duality gap at the μ center.

Lemma 11. *One has $(x^+)^T s^+ = n\mu$.*

Proof. Because of Equations (19) and (21), we have

$$\begin{aligned} x^+ s^+ &= (x + \Delta x)(s + \Delta s) \\ &= xs + (x\Delta s + s\Delta x) + \Delta x\Delta s \\ &= \mu e + \Delta x\Delta s = \mu(e + \dot{x}\dot{s}). \end{aligned}$$

Since the vectors $\dot{x}$ and $\dot{s}$ are orthogonal, we get

$$\begin{aligned} x^{+T} s^+ &= e^T (x^+ s^+) = \mu e^T (e + \dot{x}\dot{s}) \\ &= \mu(e^T e + \dot{x}^T \dot{s}) = \mu n, \end{aligned}$$

proving the lemma.

Primal–Dual Proximity Measure and Quadratic Convergence

In order to analyze the process of taking Newton steps, our next task is to define a suitable proximity measure for the current case. Since a strictly feasible triple (x, y, s) consists of the μ centers of (P) and (D) if

and only if $v = e$, the measure must vanish if and only if $v = e$, which happens if and only if $v^{-1} - v = 0$. Indeed, the norm of $v^{-1} - v$ seems to be a natural candidate for measuring proximity to the μ centers. Therefore, we define

$$\delta(x, s, \mu) := \frac{1}{2} \|v^{-1} - v\|. \quad (26)$$

Recall that $\dot{x}$ and $\dot{s}$ are orthogonal. Hence, from Equation (24), we obtain

$$\delta(x, s, \mu) = \frac{1}{2} \|\dot{x} + \dot{s}\| = \frac{1}{2} \sqrt{\|\dot{x}\|^2 + \|\dot{s}\|^2}.$$

Since $\delta(x, s, \mu)$ depends only on the Hadamard product xs and μ , we feel free to use the notation $\delta(xs, \mu)$ instead.

We proceed by showing that if $\delta(xs, \mu) \leq 1$ (< 1) then after a Newton step the new iterates are (strictly) feasible. This can also be expressed by saying “the Newton step is (strictly) feasible.” For the proofs in this section we need the following technical lemma.

Lemma 12. *If $\delta := \delta(xs, \mu)$, then one has*

- (i) $\|\dot{x}\dot{s}\|_\infty \leq \delta^2$;
- (ii) $\|\dot{x}\dot{s}\| \leq \sqrt{2}\delta^2$.

Proof. We may write

$$\dot{x}\dot{s} = \frac{1}{4}((\dot{x} + \dot{s})^2 - (\dot{x} - \dot{s})^2). \quad (27)$$

From this we derive the componentwise inequality

$$-\frac{1}{4}(\dot{x} - \dot{s})^2 \leq \dot{x}\dot{s} \leq \frac{1}{4}(\dot{x} + \dot{s})^2.$$

This implies

$$-\frac{1}{4}\|\dot{x} - \dot{s}\|^2 e \leq \dot{x}\dot{s} \leq \frac{1}{4}\|\dot{x} + \dot{s}\|^2 e.$$

Since $\dot{x}$ and $\dot{s}$ are orthogonal, the vectors $\dot{x} - \dot{s}$ and $\dot{x} + \dot{s}$ have the same norm. Since this norm equals 2δ the first inequality in the

lemma follows. For the second inequality we derive from Equation (27) that

$$\begin{aligned}\|\dot{x}\dot{s}\|^2 &= e^T(\dot{x}\dot{s})^2 = \frac{1}{16}e^T((\dot{x} + \dot{s})^2 - (\dot{x} - \dot{s})^2)^2 \\ &\leq \frac{1}{16}e^T((\dot{x} + \dot{s})^4 + (\dot{x} - \dot{s})^4).\end{aligned}$$

Since $e^T z^4 \leq \|z\|^4$ for any $z \in \mathbb{R}^n$, we obtain

$$\|\dot{x}\dot{s}\|^2 \leq \frac{1}{16}(\|\dot{x} + \dot{s}\|^4 + \|\dot{x} - \dot{s}\|^4). \quad (28)$$

Using again that $\|\dot{x} - \dot{s}\| = \|\dot{x} + \dot{s}\| = 2\delta$, the second inequality follows.

Lemma 13. *If $\delta(xs, \mu) \leq 1$, then $e + \dot{x}\dot{s} \geq 0$. Moreover, if $\delta(xs, \mu) < 1$, then $e + \dot{x}\dot{s} > 0$.*

Proof. This is an immediate consequence of part (i) of Lemma 12.

Lemma 14. *The Newton step is feasible if $\delta(xs, \mu) \leq 1$ and strictly feasible if $\delta(xs, \mu) < 1$.*

Proof. To prove (strict) feasibility of x^+ it suffices to show that x^+ is nonnegative (positive), and a similar statement for s^+ holds. Using Equation (21) we obtain

$$x^+ = x + \Delta x = x + xv^{-1}\dot{x} = xv^{-1}(v + \dot{x}) \quad (29)$$

$$s^+ = s + \Delta s = s + sv^{-1}\dot{s} = sv^{-1}(v + \dot{s}). \quad (30)$$

Since x , s , and v are positive vectors, it therefore suffices to show that if $\delta(xs, \mu) \leq 1 (< 1)$ then $v + \dot{x}$ and $v + \dot{s}$ are nonnegative (positive). To this end, we introduce a step size α with $0 \leq \alpha \leq 1$, and define

$$v_x^\alpha := v + \alpha\dot{x}$$

$$v_s^\alpha := v + \alpha\dot{s}.$$

Then, we have $v_x^0 = v_s^0 = v$, and $v_x^1 = v + \dot{x}$ and $v_s^1 = v + \dot{s}$. It follows from Equation (24) that

$$\begin{aligned}v_x^\alpha v_s^\alpha &= (v + \alpha\dot{x})(v + \alpha\dot{s}) \\ &= v^2 + \alpha v(\dot{x} + \dot{s}) + \alpha^2 \dot{x}\dot{s} \\ &= (1 - \alpha)v^2 + \alpha e + \alpha^2 \dot{x}\dot{s}.\end{aligned}$$

Now let $\delta(xs, \mu) \leq 1$. By Lemma 13, we then have $\dot{x}\dot{s} \geq -e$. Substitution gives

$$\begin{aligned}v_x^\alpha v_s^\alpha &\geq (1 - \alpha)v^2 + \alpha e - \alpha^2 e \\ &= (1 - \alpha)(v^2 + \alpha e).\end{aligned}$$

If $0 \leq \alpha < 1$, the last vector is positive. So, we have

$$v_x^\alpha v_s^\alpha > 0, \alpha \in [0, 1).$$

Since the entries of v_x^α and v_s^α depend continuously on α , and they are positive for $\alpha = 0$, it follows that they will be positive for $\alpha \in [0, 1)$, and therefore nonnegative for $\alpha \in [0, 1]$. Hence, $v_x^1 = v + \dot{x} \geq 0$ and $v_s^1 = v + \dot{s} \geq 0$, proving the first statement in the lemma.

Finally, if $\delta(xs, \mu) < 1$, then Lemma 15 implies that $\dot{x}\dot{s} > -e$, whence we obtain $v_x^\alpha v_s^\alpha > 0$ for $\alpha \in [0, 1]$. The same continuity argument yields that $v_x^1 = v + \dot{x} > 0$ and $v_s^1 = v + \dot{s} > 0$. Hence, the proof is complete.

We are now ready to prove that the Newton process is quadratically convergent.

Lemma 15. *If $\delta := \delta(xs, \mu) < 1$, then*

$$\delta(x^+ s^+, \mu) \leq \frac{\delta^2}{\sqrt{2(1 - \delta^2)}}.$$

Proof. According to the definition of $\delta(x^+ s^+, \mu)$, we have

$$\begin{aligned}2\delta(x^+ s^+, \mu) &= \|(v^+)^{-1} - v^+\| \\ &= \|(v^+)^{-1}(e - (v^+)^2)\| \\ &\leq \frac{\|e - (v^+)^2\|}{v_{\min}^+},\end{aligned}$$

where $v_{\min}^+$ denotes the smallest entry in v^+ , the (positive!) vector given by

$$v^+ = \sqrt{\frac{x^+ s^+}{\mu}}.$$

Using Equations (29) and (30), and $xs = \mu v^2$, we get

$$\begin{aligned} x^+ s^+ &= xv^{-1}(v + \dot{x}) \cdot sv^{-1}(v + \dot{s}) \\ &= \mu(v + \dot{x})(v + \dot{s}), \end{aligned}$$

whence it follows that $(v^+)^2 = (v + \dot{x})(v + \dot{s})$. Also using Equation (24), we obtain

$$\begin{aligned} (v^+)^2 &= v^2 + v(\dot{x} + \dot{s}) + \dot{x}\dot{s} \\ &= v^2 + v(v^{-1} - v) + \dot{x}\dot{s} \\ &= e + \dot{x}\dot{s}. \end{aligned}$$

This implies that $e - (v^+)^2 = -\dot{x}\dot{s}$ and $v_{\min}^+ \geq \sqrt{1 - \|\dot{x}\dot{s}\|_\infty}$. Substitution gives

$$2\delta(x^+ s^+, \mu) \leq \frac{\|\dot{x}\dot{s}\|}{\sqrt{1 - \|\dot{x}\dot{s}\|_\infty}}.$$

Now applying the bounds in Lemma 12, we obtain

$$2\delta(x^+ s^+, \mu) \leq \frac{\sqrt{2}\delta^2}{\sqrt{1 - \delta^2}},$$

which implies the inequality in the lemma.

As a result we have the following corollary.

Corollary 5. *If $\delta(xs, \mu) < \frac{1}{\sqrt{2}}$, then $\delta(x^+ s^+, \mu) \leq \delta(xs, \mu)^2$.*

Updating the Barrier Parameter

We proceed by considering the effect on the proximity measure of an update of the barrier parameter from μ to $\mu^+ = (1 - \theta)\mu$. Note that contrary to the corresponding results for the primal and dual method (cf. Lemmas 3 and 7), this time we have an equality in the “updating” lemma.

Lemma 16. *Let (x, y, s) be a strictly feasible triple and $\mu > 0$ such that $x^T s = n\mu$. Moreover, let $\delta := \delta(xs; \mu)$ and $\mu^+ = (1 - \theta)\mu$, with $\theta < 1$. Then*

$$\delta(xs; \mu^+)^2 = (1 - \theta)\delta^2 + \frac{\theta^2 n}{4(1 - \theta)}.$$

Proof. Let $\delta^+ := \delta(xs; \mu^+)$ and, as usual, $v = \sqrt{xs/\mu}$. Then, by definition,

$$\begin{aligned} 2(\delta^+)^2 &= \left\| \sqrt{1 - \theta}v^{-1} - \frac{v}{\sqrt{1 - \theta}} \right\|^2 \\ &= \left\| \sqrt{1 - \theta}(v^{-1} - v) + \frac{\theta v}{\sqrt{1 - \theta}} \right\|^2. \end{aligned}$$

From $x^T s = n\mu$, it follows that $\|v\|^2 = n$. Hence, v is orthogonal to $v^{-1} - v$, because

$$v^T(v^{-1} - v) = n - \|v\|^2 = 0.$$

Therefore,

$$4(\delta^+)^2 = (1 - \theta)\|v^{-1} - v\|^2 + \frac{\theta^2 \|v\|^2}{1 - \theta}.$$

Finally, since $\|v^{-1} - v\| = 2\delta$ and $\|v\|^2 = n$, the result follows.

Primal–Dual Interior-Point Method

Assuming that we have strictly feasible triple (x, y, s) and $\mu > 0$ such that $x^T s = n\mu$ and $\delta(xs, \mu) < 1/2$, the following lemma provides a numerical method to follow the central path approximately.

Lemma 17. *Let $x^T s = n\mu$ and $\delta(xs, \mu) \leq 1/2$. If we first update μ to $\mu^+ = (1 - \theta)\mu$, with $\theta = 1/\sqrt{2n}$ and then perform a Newton step, the resulting triple (x^+, y^+, s^+) is such that $(x^+)^T s^+ = n\mu^+$ and $\delta(x^+ s^+, \mu^+) \leq 1/2$.*

Proof. After the barrier parameter update we have, by Lemma 16,

$$\begin{aligned} \delta(xs; \mu^+)^2 &= (1 - \theta)\delta(xs, \mu)^2 + \frac{\theta^2 n}{4(1 - \theta)} \\ &\leq \frac{1 - \theta}{4} + \frac{1}{8(1 - \theta)}. \end{aligned}$$

The right-hand side is convex in θ for $\theta < 1$. It achieves its maximum value $3/8$ on $[0, 1/2]$ at one of the end points of the interval. We conclude from this that $\delta(xs; \mu^+)^2 \leq 3/8$. Since $\delta(xs; \mu^+) \leq \sqrt{3/8} < 1/\sqrt{2}$ we may apply Corollary 5, which gives $\delta(x^+ s^+, \mu^+) \leq \delta(xs; \mu^+)^2$. Hence, we have $\delta(x^+ s^+, \mu^+) \leq \frac{1}{2}$.

By Lemma 11, we also have $(x^+)^T s^+ = n\mu^+$. Hence, the proof is complete.

The primal–dual algorithm can now be stated as shown below.

Algorithm 3. A full-Newton step primal–dual IPM or LO

Input:

(x^0, y^0, s^0) strictly feasible and $\mu^0 > 0$ such that $\delta(x^0 s^0, \mu^0) \leq \frac{1}{2}$ and $(x^0)^T s^0 = n\mu^0$;
accuracy parameter $\varepsilon > 0$;
barrier update parameter $\theta, 0 < \theta < 1$;

begin

$x := x^0; y := y^0; s := s^0; \mu := \mu^0$;

while $x^T s > \varepsilon$

$\mu := (1 - \theta)\mu$;

$(x, y, s) := (x, y, s) + (\Delta x, \Delta y, \Delta s)$;

endwhile

end

We conclude this section by deriving an iteration bound for the algorithm.

Theorem 3. Taking $\theta = \frac{1}{\sqrt{2n}}$, the algorithm requires no more than

$$\sqrt{2n} \log \frac{n\mu^0}{\varepsilon}$$

iterations. The last generated triple (x, y, s) is strictly feasible, whereas $x^T s \leq \varepsilon$.

Proof. By Lemma 17, the triple (x, y, s) will be strictly feasible and $\delta(xs, \mu) \leq \frac{1}{2}$, after each iteration of the algorithm and, moreover, $x^T s = n\mu$. Therefore, the algorithm will stop if $n\mu \leq \varepsilon$. After the k th iteration, we have $\mu = (1 - \theta)^k \mu^0$. Using exactly the same arguments as in the proof of Theorem 1, the iteration bound in the current theorem follows. Owing to the stopping criterion in the algorithm at termination, we have $x^T s \leq \varepsilon$. Hence, the proof is complete.

SPEEDING UP THE ALGORITHMS

The iteration bounds of the primal, dual, and primal–dual algorithms that we presented stem from the reduction of the parameter μ at each iteration by the factor $1 - \theta$. In practical situations, n may be (very) large and then this factor is so close to 1 that the number of iterations that is necessary to

achieve a sufficiently accurate solution will be very large. Owing to the high computational cost per iteration, that is required to compute the search direction, the algorithms may turn out to be far from efficient. In this section we discuss some remedies for the primal–dual algorithm, but similar arguments apply to the primal algorithm and the dual algorithm. We choose the primal–dual algorithm in our discussion; it is the most popular algorithm because the most efficient in many cases.

Adaptive Updating

When implementing the primal–dual IPM presented in the section titled “Primal–Dual Method”, it turns out that Newton’s method is much more accurate than predicted by the theory. As a result, the value of the proximity measure after each iteration is usually much smaller than $\frac{1}{2}$. Note that by Lemma 17 the algorithm remains well defined as long as after each iteration $\delta(xs, \mu) \leq 1/2$ holds. This indicates that larger reductions of the barrier parameter are possible, provided that one takes care that the above condition on the proximity measure remains satisfied. For a detailed discussion of this idea, we refer to Roos *et al.* [5, Section 7.6].

Large-Updates

We may enforce much larger reductions in μ by taking, for example, $\theta = 0.5$ or even $\theta = 0.99$, at each iteration. This method, which is most used in practice, significantly

reduces the number of iterations. Unfortunately, it is then no longer possible to guarantee that the new iterates remain in the vicinity of the center $x(\mu)$, as measured by the distance $\delta(x, \mu)$. Even worse, if $\delta(x, \mu) > 1$, it may happen that the new iterates are no longer feasible (because having negative entries). This may be prevented by not taking the full-Newton step, but use a damping factor that forces the iterates to remain strictly feasible. In this approach, $\delta(x, \mu)$ becomes useless for measuring the distance to the μ center, because we have convergence results only for $\delta(x, \mu) \leq 1$. However, we may take profit of the fact that the Newton direction is a descent direction for the so-called primal-dual logarithmic barrier function. This function is obtained by adding the primal logarithmic barrier function and minus the dual logarithmic barrier function:

$$\begin{aligned} f_{PD}(x, y, s, \mu) \\ &:= f_P(x; \mu) - f_D(y; \mu) \\ &= \frac{c^T x - b^T y}{\mu} - \sum_{i=1}^n \log x_i - \sum_{i=1}^n \log s_i. \end{aligned}$$

Since $f_P(x; \mu)$ is strictly convex and $f_D(y; \mu)$ strictly concave, this function is strictly convex and its unique minimizer on the feasible domain is the triple $(x(\mu), y(\mu), s(\mu))$. So, its minimal value is given by

$$\begin{aligned} f_{PD}(x(\mu), y(\mu), s(\mu), \mu) &= \frac{c^T x(\mu) - b^T y(\mu)}{\mu} \\ &\quad - \sum_{i=1}^n \log x_i(\mu) s_i(\mu) \\ &= n - n \log \mu. \end{aligned}$$

where we used Equation (11) and $x_i(\mu)s_i(\mu) = \mu$ for each i . Hence, defining

$$\begin{aligned} \Psi(x, s, \mu) &:= f_{PD}(x, y, s, \mu) \\ &\quad - f_{PD}(x(\mu), y(\mu), s(\mu), \mu), \end{aligned}$$

and using Lemma 1 we obtain

$$\Psi(x, s, \mu) = \frac{x^T s}{\mu} - \sum_{i=1}^n \log x_i s_i - n + n \log \mu. \quad (31)$$

This barrier function has the triple $(x(\mu), y(\mu), s(\mu))$ as its minimizer on the feasible domain, where its value equals zero.

Assuming $\delta(xs, \mu) \leq 1$, after updating μ to $(1 - \theta)\mu$, we have $\Psi(x, s, \mu) = O(n)$. It has been shown by many authors that by doing a line search along the primal-dual Newton direction, the value of $\Psi(x, s, \mu)$ can be decreased by at least a fixed constant, independent of (x, y, s) and n . The line search will keep the iterates certainly strictly feasible, because at the boundary of the feasible domain $\Psi(x, s, \mu)$ becomes infinite. It follows that only $O(n)$ damped recentering steps will suffice to reach an iterate x in the vicinity of the μ center, for example, for which $\delta(xs, \mu) < 1$. The resulting iteration bound of a suitable variant of this method is $O(n \log(n\mu^0/\varepsilon))$. For a detailed discussion of this method, we refer to Roos *et al.* [5], Vanderbei [6], Wright [7], and Ye [8] and their references.

Despite the worse theoretical iteration bound (by a factor $\sqrt{n}$), the so-called *large-update methods* are in practice much more efficient than the full step methods presented in the previous sections. This phenomenon has been called the *irony of IPMs* [12].

The large-update variant of the primal method is very much in the spirit of the classical barrier method, as presented by Gill *et al.* [13], though these authors did not find a polynomial-time iteration bound for their method.

HISTORY OF THE CHILEAN INSTITUTE OF OPERATIONS RESEARCH

In 1966 ENDESA's¹ CEO Renato Salazar together with managers from other important companies or institutions, such as IANSA, CAP, ENAP, and CIENES invited professionals working with OR models to a meeting where they wanted to share experiences related to mathematical models for decision making in Chilean industry. Participants at this meeting agreed on the creation of a society promoting applied OR models; ICHIO, the Chilean Institute of Operations Research was born.

In 1967, after having organized its first congress, ICHIO's first president, secretary, and board of directors were elected as shown in the following table (Table 1).

This team worked on ICHIO's legal structure which was presented to the Ministry of Justice on April 30, 1968. In 1975, ICHIO

was accepted as member society of the International Federation of Operations Research (IFORS).

Today, ICHIO is governed by its president, past president, secretary, treasurer, and two directors. Its approximately 40 individual members come mainly from 15 Chilean universities.

ACCOMPLISHMENTS

ICHIO serves as a facilitator for the development of OR in Chile. Its meetings gather Chilean researchers working in related areas. ICHIO's journal has published mostly scientific articles, describing latest developments from operations research (OR) and neighboring fields. It has undergone a major redesign and will be published from 2010 on as an electronic journal.

In 2008, the first student chapter within ICHIO was created by students from the Universidad de Concepción. We plan to have such chapters in the main Chilean cities where OR is taught. The main goal of these chapters is to attract students interested in OR-related topics to ICHIO's activities at an early stage of their university education.

In 2009, ICHIO launched a new version of its web site (www.ichio.cl) with interactive material regarding different topics of OR, free for public use. Each such area is maintained by its editor who is responsible for the respective content.

MEETINGS OF THE CHILEAN INSTITUTE OF OPERATIONS RESEARCH

The main meeting hosted by ICHIO is its biannual congress Optima with approximately 150 to 200 participants. At these events usually there are plenary and semiplenary presentations, regular sessions, and poster presentations. Participants come mainly from Chile but also from several

¹All abbreviations in this text are expanded in the appendix.

Table 1. ICHIO's First President, Secretary, and Board of Directors

President	Oscar Barros, Department of Industrial Engineering, Universidad de Chile

Latin-American countries, and in some cases from northern America, Europe, or Australasia. The beauty of the Chilean landscape makes it particularly attractive for foreign scientists to combine the congress with some days of vacations.

As ICHIO's strategy, since 1995 its congresses generally take place outside the capital Santiago where most of the scientific activities are concentrated at the major universities. This way a better dissemination of OR to remote places of this highly centralized and densely populated country is achieved.

Consequently, the Optima congresses are particularly interesting for local faculty members, professionals, and students from engineering, mathematics, computer science, and related areas. The following table (Table 2) displays information about the series of past Optima congresses.

The congress Optima 2011 will take place in October 2011 in *Pucon* organized by the *Universidad de la Frontera*.

The Latin-American operations research society (ALIO) organizes summer schools mainly for graduate students from OR and related fields. Chile hosted these summer schools twice: in 1994 in *Punta de Talca* and in 2001 in *Viña del Mar*.

Approximately twice a year, ICHIO organizes its local colloquia with usually two academic talks open to the general public and a subsequent meeting of its members. These talks are particularly interesting for students and faculty members at the host university.

Puerto Montt	Universidad de Los Lagos	2007
Termas de Chillan	Universidad del Bio Bio	2009

SUCCESSFUL APPLICATIONS

During the first Optima Congress organized by ICHIO in 1967 the following applications were presented:

- "Planning model for expanding the beet sugar industry in Chile" by Professor Juan Gutierrez
- "Logistic models for material handling in the Chilean steel industry" by Sergio Alvarez
- "Optimizing process in the Chilean oil refinery industry" by George Nascimento
- "OR: A necessary discipline for engineering education" by Dr. Enrique Cansado.

From then on, ICHIO members developed and implemented many successful

applications in industry and government. The following list of papers from the journal "Interfaces" gives an idea of the impact OR had in Chile in a broad sense. In each case we list title, reference, and a shortened version of the abstract as it appears in the paper.

- *Competitive Cost Dynamics* [1]. This is the first of three articles about some popular tools that have been widely used since the early 1970s to support strategic decision making.
- *Growth–Share Matrix in Strategic Planning* [2]. In the second of a series of three tutorials, the methodology and strategic implications of the portfolio business matrix are analyzed and illustrations given of the use of the growth–share matrix.
- *Industry Attractiveness–Business Strength Matrix in Strategic Planning* [3]. In the third and final paper in a series of tutorials on strategic planning, the industry attractiveness–business strength matrix is presented with a detailed procedure for its application, variety of examples, and a discussion of its strengths and weaknesses.
- *Corporate Strategic Planning Process* [4]. Described is an approach to develop a formal corporate strategic planning process in a business firm.
- *Concept of Strategy and the Strategy Formation Process* [5]. The concept of strategy is presented as a normative model that has validity for all firms.
- *Truck Scheduling* [6]. An operative and computerized system, ASICAM, based on a simulation process with heuristic rules, to support daily truck scheduling decisions has been developed.
- *OR Models and the Management of Agricultural and Forestry Resources* [7]. Over the last two decades, forest land management practices have changed in response to ecological issues and the need to improve efficiency to remain competitive in emerging global markets. Decision processes have become more open and complex as information and communication technologies change. The OR/MS community is meeting these challenges by developing new modeling strategies, algorithms, and solution procedures that address spatial requirements, multiresource planning, hierarchical systems, multiple objectives, and uncertainty as they pertain to both industrial timberlands and public forests.
- *Optimal Investment Policies for Pollution Control in the Copper Industry* [8]. A decision support system for investment projects in pollution abatement plants at state-owned copper smelters in Chile has been developed. A mixed-integer linear model was formulated to determine the optimal investment policy for this interrelated production–environmental problem.
- *Strategic Valuation of Investment under Competition* [9]. The most serious problem with the widely used discounted cash flow (DCF) methods of investment valuation is that they are commonly applied without explicit regard to competition. As a result, the prescriptions they afford are often inconsistent with those given by competitive strategy frameworks. To remedy this, such frameworks have been integrated with DCF methods to value investments (and disinvestments) in competitive and uncertain contexts.
- *OR Systems in the Chilean Forest Industries* [10]. The Chilean forestry sector is composed of private firms that combine large timber-land holdings of mostly pine plantations and some eucalyptus with sawmills and pulp plants. Since 1988, to compete in the world market, the main Chilean forest firms, which have sales of about \$1 billion, have started implementing OR models developed jointly with academics from the University of Chile. These systems support decisions on daily truck scheduling, short-term harvesting, location of harvesting machinery and access roads, and medium- and long-term forest planning. Approaches used in solving these complex problems include simulation,

linear programming with column generation, mixed-integer LP formulations, and heuristic methods. The systems have led to a change in organizational decision making and to estimated gains of at least US \$20 million per year.

- *Production Planning Decision Support System (DSS) [11]*. An optimization-based decision support systems (OBDSSs) to support production planning at CTI (an appliance-manufacturing firm) using new methodologies and tools based on structured modeling has been developed and implemented.
- *Assignment of Catering Contracts [12]*. Chile's school system is using mathematical modeling to assign catering contracts in a single round sealed-bid combinational auction.
- *Mathematical Programming Combined with Expert Systems Improves Customer Service [13]*. Determining what fertilizer mix to apply to certain soils is complicated and time consuming. A hybrid tool using expert system technology and mixed-integer linear programming models that increased fertilizer sales has been proposed.
- *Programming of the Copper Smelting Process [14]*. A model to maximize production while respecting metallurgic, operational, environmental, and other restrictions has been developed. Two methods of planning daily activities for the plant were proposed.
- *OR Models and the Management of Agricultural and Forestry Resources [15]*. OR has helped people to understand and manage agricultural and forestry resources during the last 40 years. Its use to assess the past performance of OR models in this field and to highlight current problems and future directions of research and applications has been analyzed.
- *Mixed-Integer Programming Models for Sports Scheduling [16]*. Since 2005, Chile's professional soccer league has used a game-scheduling system that is based on an integer linear programming model. The Chilean league managers considered several operational, economic, and sporting criteria for the final tournaments' scheduling. Thus, they created a highly constrained problem that had been, in practice, unsolvable using their previous methodology. This led to the adoption of a model that used some techniques that were new in soccer league sports scheduling. The schedules they generated provided the teams with benefits such as lower costs, higher incomes, and fairer seasons. In addition, the tournaments were more attractive to sports fans. The success of the new scheduling system has completely fulfilled the expectations of the "Asociación Nacional de Fútbol Profesional" (ANFP), the organization for Chilean professional soccer.
- *Operations Research in Mine Planning [17]*. Applications of operations research to mine planning date back to the 1960s. Since that time, optimization and simulation, in particular, have been applied to both surface and underground mine planning problems, including mine design, long- and short-term production scheduling, equipment selection, and dispatching, inter alia. This article reviews several decades of such literature with a particular emphasis on more recent work, suggestions for emerging areas, and highlights of successful industrial applications.
- *Course Scheduling System for Executive Education [18]*. Each October, the Executive Education Unit at the Universidad de Chile develops its course schedules for the following year. By 2008, the complexities of increasing enrollments and course offerings had rendered its manual timetabling process unmanageable. This article presents an automated computational system that generates optimal timetables and classroom assignments for all the unit's courses, minimizing both operating costs and schedule conflicts.

FUTURE CHALLENGES

According to the most recent study performed following the Knowledge Assessment Methodology developed by the World Bank (www.worldbank.org/kam), Chile ranked 43 in Innovation and 47 in Education. There is a clear need to improve in those sectors if Chile wants to increase its productivity and take the step to become a developed country. Advanced OR and its applications play a crucial role on this road and ICHIO will contribute to reach this goal by dissemination of OR techniques and applications.

For the period 2010–2015 ICHIO has the following goals.

- ICHIO will try to increase membership. By mid-2009 ICHIO had about 50 individual members. At the biannual congress Optima 2009 membership of students as well as organizations was introduced. By the end of 2015 we want to have at least 50 student members, 100 individual professional members, and 5 corporate members.
- ICHIO will improve its links with industry since more fluent communication between academia and industry is necessary in order to inject OR into practice on the one hand. On the other hand, this integration helps to better identify real problems that need advanced solutions. The aforementioned corporate membership is one step in this direction. We will also have colloquia at companies and increase practitioners' participation at our Optima congresses.
- ICHIO will establish exchange agreements with its sister societies in Latin-American countries. A first contract with EPIO from Argentina has been signed recently in 2009; the agreement with the Brazilian OR society SOBRAPO is currently under development and will be signed in 2010. This kind of agreement will improve dissemination of research results via increased participation in the respective conferences and journals.
- Along the lines of the previous item, it is intended to have joint conferences

hosted by ICHIO and some affiliated societies.

- The journal published by ICHIO has been redesigned and will appear from 2010 on as an electronic journal. It is our goal to get at least an indexation in SCIELO by 2015.

Acknowledgments

Many ICHIO members have contributed to the developments described in this short article. They deserve special thanks. Support from the Chilean "*Instituto Sistemas Complejos de Ingeniería*" (ICM: P-05-004-F, CONICYT: FBO16) is gratefully acknowledged; (www.sistemasdeingenieria.cl).

CHINESE POSTMAN PROBLEM

WANYAN YU

RAJAN BATTA

Department of Industrial and
Systems Engineering,
University at Buffalo (State
University of New York),
Buffalo, New York

CHINESE POSTMAN PROBLEM BASICS

Chinese postman problem (known as *CPP*) is a branch of arc routing problems. It was first studied by the Chinese mathematician Meigu Guan (or Kwan Mei-ko) when he worked as a post office worker during the Chinese cultural revolution. Guan stated: "A mailman has to cover his assigned segment before returning to the post office. The problem is to find the shortest walking distance for the mailman." [1]. In general, the CPP is to determine a closed walk of minimum cost or length covering each arc at least once. The earliest origin of CPP is the Königsberg bridge problem (see Fig. 1), which is to determine whether there exists a closed walk traversing each of the seven bridges exactly once. Leonhard Euler [2] solved the problem in 1736 by finding a necessary and sufficient condition for the existence of such a walk on any connected undirected graph, and proved that there is no solution for this particular problem. A graph with the same property is therefore called *Eulerian graph* and the closed path found on the graph is called *Eulerian tour* (Eulerian circuit or Eulerian cycle). A formal definition of an Eulerian graph is as follows: an Eulerian graph indicates that there exists a closed path on the graph that contains each arc exactly once and each vertex at least once. We note that the definition of an Eulerian graph is not restricted to a connected undirected graph.

The relationship between a CPP solution and an Eulerian tour is explained below. If

a graph is an Eulerian graph, the solution of a CPP (named *CP tour*) for the graph is simply the Eulerian tour. Otherwise, some edges must be traversed more than once in order to cover the graph, and the CP tour is the shortest among these edge-covering tours. Therefore, if a graph can be revised to an Eulerian graph by adding a set of arcs with minimum cost (called a *subproblem of augmentation*), then the solution of a CPP for the original graph can be found by finding an Eulerian tour on the revised graph. The scope of this article includes a discussion of CPP on different types of graphs (e.g., directed graphs and mixed graphs), and we will examine how CPP can be solved by converting a graph to a Eulerian graph for each graph type.

As mentioned above, algorithms for the CPP include two stages. The first stage is to find the least-cost set of repeated arcs or edges which makes the graph Eulerian. The second stage is to find the actual sequence of the traversed arcs or edges. It is proved that given the set found in stage one, the traversing sequence can be determined in polynomial time [3]. Therefore, the computational complexity depends on the subproblem of augmentation in the first stage.

Most applications of CPP relate to arc routing problems, such as mail delivery, garbage collection, snow plows, highway lawnmowers, and school bus routing [4]. Other than conventional routing applications, there are several other problems that have a similar mathematical model to that of the CPP. Examples of these problems include topological testing of computer networks, design of VLSI (very-large-scale-integration) tours of integrated circuit to minimize the number of ways of connecting different layers [5], analysis of DNA [6], and transmission line inspections.

The next section provides a classification for CPP and presents the available mathematical models and exact algorithms or heuristics for each class of problems. We

Figure 1. The seven bridges of Königsberg.

note that this classification is similar to that found in the paper by Eiselt *et al.* [3].

CHINESE POSTMAN PROBLEM CLASSES

Based on the type of graphs it solves, CPP can be classified into the following five types: the undirected Chinese postman problem (UCPP), the directed Chinese postman problem (DCPP), the mixed Chinese postman problem (MCP), the windy postman problem (WPP), and the hierarchical CPP (HPP). For instance, MCP solves CPP on mixed graphs that include both undirected and directed arcs. WPP refers to the problem of undirected graphs, while the cost of traversing an edge is different for the two directions of travel. The last type is hierarchical CPP, where a precedence relation constraint is enforced to the set of arcs. This precedence relation defines either a partial or a complete order of the arcs needed to be traversed. In the literature, the UCPP and DCPP have been well studied and solved in polynomial time. However, the other types of CPP are proved to be NP-hard problems and are still relatively unexplored.

As a general representation of graphs, let $G = (V, A)$ be a connected graph without loops, where $V = \{v_1, \dots, v_n\}$ is the vertex set and $A = \{(v_i, v_j) : v_i, v_j \in V \text{ and } i \neq j\}$ is the arc set. If a graph is undirected, the arc set is equivalent to an edge set. For every arc, there is a nonnegative cost (distance, or length) c_{ij} associated with it, where $c_{ij} = \infty$ if the arc is not defined. These five problems

are discussed in the following subsections, respectively.

Undirected Chinese Postman Problem (UCPP)

The CPP defined on an undirected graph is classified as an undirected CPP (UCPP). The Eulerian property is central to the solution of the UCPP, where an Eulerian graph indicates that there exists a closed path in G that contains each arc exactly once.

Guan [1] observed that G always has an even number of odd-degree vertices and that an Eulerian graph G' can be derived from G by adding edges to link odd-degree vertices. Guan proved that the necessary and sufficient condition for the optimality of an Eulerian tour on G' is that there is no redundancy, that is, a CP tour will never utilize an edge more than twice. Therefore, the length of the CP tour will not exceed twice of the length of graph G .

The UCPP is usually formulated as an integer programming model in the first stage and the objective is to determine a minimum increase of cost of G into G' such that all vertices of G' have an even degree. Let x_{ij} be the number of additional copies of (v_i, v_j) in the tour. Let $\delta(i)$ be the set of edges incident to v_i , and let $T \subseteq V$ be the set of odd-degree vertices of V . Then, the formulation for UCPP is given below.

UCPP Model 1

$$\text{Minimize } \sum_{(v_i, v_j) \in A} c_{ij} x_{ij} \quad (1)$$

$$\begin{aligned}
&\text{subject to } \sum_{(v_i, v_j) \in \delta(i)} x_{ij} \\
&= \begin{cases} 1(\text{mod } 2) & \text{if } v_i \in T \\ 0(\text{mod } 2) & \text{if } v_i \in V \setminus T \end{cases} \\
&\quad (2)
\end{aligned}$$

$$x_{ij} \in \{0, 1\} \quad ((v_i, v_j) \in A). \quad (3)$$

This model can be solved as a minimum weight perfect matching problem over the odd-degree vertex set T . Graph G' with the shortest length of tour is then obtained by adding edges in the matching to G . The matching problem is solved by Lawler [7] using an $O(|V|^3)$ algorithm. More results with less computational complexity can be found in Refs 8 and 9.

An equivalent model of UCPP is proposed by Edmonds and Johnson [10]. A set of edges $E(S) = \{(v_i, v_j) : v_i \in S, v_j \in V \setminus S \text{ or } v_i \in V \setminus S, v_j \in S\}$ is defined such that any edge in the set meets one vertex in S and one vertex not in S , where S is a nonempty proper subset of V containing an odd number of odd-degree vertices. Then, the model is given below.

UCPP Model 2

$$\text{Minimize } \sum_{(v_i, v_j) \in A} c_{ij} x_{ij} \quad (4)$$

$$\begin{aligned}
&\text{subject to } \sum_{(v_i, v_j) \in E(S)} x_{ij} \geq 1 \\
&\quad (S \subset V, S \text{ odd}) \quad (5)
\end{aligned}$$

$$x_{ij} \geq 0 \quad ((v_i, v_j) \in A) \quad (6)$$

$$x_{ij} \text{ integer } ((v_i, v_j) \in A). \quad (7)$$

Constraint (5), known as *blossom inequalities*, are defined for every odd set S . It is equivalent to the statement that each odd-degree vertex must be made even by adding edges incident to it. Edmonds and Johnson solved this model by adapting Edmonds' blossom algorithm for matching problems.

Two algorithms for finding the Eulerian tour after obtaining the Eulerian

graph G' are presented below. The first algorithm is referred to as *Fleury's algorithm*, which dates to 1883. The second algorithm is developed by Edmonds and Johnson in Ref. 10.

Fleury's Algorithm.

Step 0. Select an arbitrary vertex v_i .

Step 1. Select an edge (v_i, v_j) such that the deletion of this edge does not disconnect the graph. Then delete edge (v_i, v_j) from the graph. Set $v_i = v_j$.

Step 2. Repeat step 1 until all edges have been deleted. These deleted edges in sequence form an Eulerian tour.

End-Pairing Algorithm.

Step 0. Trace out a simple tour which may not include all edges. If the tour includes all edges, stop and declare it to be Eulerian.

Step 1. Begin at any vertex v on the tour incident to edges not in the tour and complete the second simple tour not including any edge on the first tour.

Step 2. Inject the second tour into the first tour by swapping the edge pairing in the two tours. That is, if e_0 is the first edge leaving vertex v and e_L is the last edge entering vertex v , then for any edge pair (e_1, e_2) of the first tour meeting v , swap the edge pairings by replacing (e_1, e_2) by (e_1, e_0) and (e_L, e_2) . If all edges are included in the newly formed tour, stop. Otherwise, go to step 1.

Fleury's algorithm is straightforward but time consuming. However, the algorithm proposed by Edmonds and Johnson improves the computational complexity to $O(|V|)$. Readers are referred to [11] for additional algorithms for finding Eulerian tours on an Eulerian graph.

Directed Chinese Postman Problem (DCPP)

The CPP defined on a directed graph is classified into this type. Note that different from the UCPP that always has a solution, the

Figure 2. A strongly connected graph.

directed graph must be strongly connected for the existence of a solution to the DCP. An example of a strongly connected graph is shown in Figure 2, where there is a path from each vertex on the graph to every other vertex. In a directed graph, a vertex is called *unbalanced* if the number of arcs coming into it does not equal that going out from it. For example, all the vertices in Fig. 2 are unbalanced. Define I as the set of unbalanced vertices v_i with an excess of s_i incoming arcs and J the set of unbalanced vertices v_j with an excess of d_j outgoing arcs. Let c_{ij} be the length of the shortest path between v_i and v_j . Edmonds and Johnson [10], Orloff [12], and Beltrami and Bodin [13] showed that this problem can be modeled as a least-cost transportation problem where the flow on each arc has to be at least 1. The formulation is given below.

DCPP Model

$$\text{Minimize } \sum_{v_i \in I} \sum_{v_j \in J} c_{ij} x_{ij} \quad (8)$$

$$\text{subject to } \sum_{v_j \in J} x_{ij} = s_i \quad (v_i \in I) \quad (9)$$

$$\sum_{v_i \in I} x_{ij} = d_j \quad (v_j \in J) \quad (10)$$

$$x_{ij} \geq 0 \quad (v_i \in I, v_j \in J). \quad (11)$$

By adding arcs represented by solution x_{ij} to the above model, the original graph G is transferred to an Eulerian graph G' . Fleury's algorithm can then be adapted to find an Eulerian tour on G' . Another

popular algorithm to solve the Eulerian tour problem for directed graph is provided by Aardenne-Ehrenfest and de Bruijn [14]. The algorithm is given below.

van Aardenne-Ehrenfest and de Bruijn's Algorithm [14].

Step 0. Find a spanning arborescence of G rooted at any vertex v_r , where an arborescence is a directed, rooted tree such that all the edges are directed away from the root.

Step 1. At any vertex v_i except for the root v_r of the arborescence, specify any order and label the arcs directed away from v_i so long as the arc used in the arborescence is last in the ordering. For the root vertex v_r , specify any order and label the arcs directed away from it.

Step 2. Obtain an Eulerian tour by following the ordered arc from an arbitrary vertex, that is, whenever a vertex is entered, it is left through the arc not yet traversed according to an ascending order of labels. Stop until all the arcs have been included in the tour.

The proof of the algorithm providing an Eulerian tour is presented by Edmonds and Johnson in Ref. 10.

The Mixed Chinese Postman Problem (MCP)

If the CPP is defined on a graph containing both directed arcs and undirected edges, this type of CPP is called the *MCP*. Similar to previous CPP, solving MCP involves finding a minimum-cost augmentation of graph G to satisfy the necessary and sufficient conditions of an Eulerian graph, and then to determine an Eulerian path. Here, G needs to be a strongly connected graph represented as $G = (V, A \cup E)$, where A represents an arc set and E represents an edge set.

Some terminologies need to be defined over mixed graphs before presentation of MCP. A mixed graph is *even* if the total number of arcs and edges to any vertices on it is even. It is *symmetric* when any vertex has

Figure 3. Example of a graph that is not symmetric but Eulerian [3].

an equal number of incoming arcs and outgoing arcs. It is *balanced* if the balanced set conditions are satisfied [15], that is, for every $S \subseteq V$, the difference between the number of directed arcs from S to $V \setminus S$ and the number of directed arcs from $V \setminus S$ to S must be less than or equal to the number of undirected arcs joining S and $V \setminus S$. A mixed graph is balanced if it is even and symmetric. A mixed graph is Eulerian if and only if it is even and balanced, or if it is even and symmetric. However, it is noted that the symmetry is not a necessary condition for a directed mixed graph being Eulerian as described above; see Fig. 3 for an example. If a given graph G is Eulerian, the problem now becomes determination of an Eulerian tour on G . Three steps are available to achieve this goal. The first step is to assign directions to some edges in order to make G symmetric. The procedure was proposed by Ford and Fulkerson [15] to transform a mixed graph to a symmetric graph. Assigning directions to the remaining edges is completed in the second step followed by the procedure described in Eiselt *et al.* [3]. Finally, the third step is to determine an actual Eulerian tour on G by applying the van Aardenne-Ehrenfest and de Bruijn algorithm [14]. It should be noticed that it is not always feasible to determine a minimum-cost augmentation in order to solve the MCPP since some graphs cannot become Eulerian [3].

One of the formulations for MCPP is stated by Christofides *et al.* [16]. The notation needed is as follows: let (i) $A_k^+ = \{(v_i, v_j) \in A : v_i = v_k\}$, $A_k^- = \{(v_i, v_j) \in A : v_j = v_k\}$, and V_k be the set of all vertices linked to v_k by an edge; (ii) x_{ij} be the number of extra times arc (v_i, v_j) is traversed in the optimal solution; (iii) y_{ij} be the total number of times edge (v_i, v_j) is traversed from v_i to v_j ; (iv) p_k be a binary constant that equals 1 if and only if the degree of vertex v_k is odd, and 0,

otherwise; and (v) z_k be an integer variable. Then the formulation is given below.

MCPP Model 1

Minimize

$$\sum_{(v_i, v_j) \in A} c_{ij}(1 + x_{ij}) + \sum_{(v_i, v_j) \in E} c_{ij}(y_{ij} + y_{ji}) \quad (12)$$

subject to

$$\begin{aligned} & \sum_{(v_i, v_j) \in A_k^+} (1 + x_{ij}) - \sum_{(v_i, v_j) \in A_k^-} (1 + x_{ji}) \\ & + \sum_{v_j \in V_k} y_{kj} - \sum_{v_j \in V_k} y_{jk} = 0 \quad (v_k \in V) \end{aligned} \quad (13)$$

$$\begin{aligned} & \sum_{(v_i, v_j) \in A_k^+} x_{ij} + \sum_{(v_i, v_j) \in A_k^-} x_{ji} \\ & + \sum_{v_j \in V_k} (y_{kj} + y_{jk} - 1) \\ & = 2z_k + p_k \quad (v_k \in V) \end{aligned} \quad (14)$$

$$y_{ij} + y_{ji} \geq 1 \quad ((v_i, v_j) \in E) \quad (15)$$

$$z_k, x_{ij}, y_{ij}, y_{ji} \geq 0 \text{ and integer.} \quad (16)$$

An enumerative algorithm was used to solve this problem, where two different lower bounds are calculated at each node in the search tree. One is obtained by solving the minimum-cost perfect matching problem via the Lagrangian relaxation of the first constraint (13) in the above formulation, and the other is obtained by solving the minimum-cost flow problem via the Lagrangian relaxation of the third constraint (15).

Another formulation and algorithm of the MCPP were found in Nobert and Picard [17] in which they used only one variable y_{ij} for each edge of E to represent the number of copies of edge (v_i, v_j) added to the graph to make it Eulerian. For any subset S of V , following sets are defined:

$$\begin{aligned} A^+(S) &= \{(v_i, v_j) \in A : v_i \in S, v_j \in V \setminus S\}, \\ A^-(S) &= \{(v_i, v_j) \in A : v_i \in V \setminus S, v_j \in S\}, \end{aligned}$$

$$E(S) = \{(v_i, v_j) \in E : v_i \in S, v_j \in V \setminus S \text{ or } v_i \in V \setminus S, v_j \in S\}. \quad (17)$$

Furthermore, let $u(S) = |A^+(S)| - |A^-(S)| - |E(S)|$. Then the formulation is given below.

MCPM Model 2

$$\text{Minimize} \quad \sum_{(v_i, v_j) \in A} c_{ij} x_{ij} + \sum_{(v_i, v_j) \in E} c_{ij} y_{ij} \quad (18)$$

$$\text{subject to} \quad \sum_{(v_i, v_j) \in A} x_{ij} + \sum_{(v_i, v_j) \in E} y_{ij} = 2z_k + p_k (v_k \in V) \quad (19)$$

$$\begin{aligned} & - \sum_{(v_i, v_j) \in A^+(S)} x_{ij} + \sum_{(v_i, v_j) \in A^-(S)} x_{ij} \\ & + \sum_{(v_i, v_j) \in E(S)} y_{ij} \geq u(S) \\ & (S \subset V, S \neq \emptyset) \end{aligned} \quad (20)$$

$$\begin{aligned} & \sum_{(v_i, v_j) \in A^+(S)} x_{ij} + \sum_{(v_i, v_j) \in A^-(S)} x_{ij} \\ & + \sum_{(v_i, v_j) \in E(S)} y_{ij} \geq 1 (S \subset V, S \text{ odd}) \end{aligned} \quad (21)$$

$$z_k, x_{ij}, y_{ij} \geq 0 \text{ and integer.} \quad (22)$$

In this formulation, the second constraints (20) make sure that all nonempty proper subsets S of V become balanced and the third constraints (21) are a generalized form of blossom inequalities. An algorithm to solve this formulation was provided by Nobert and Picard [17]. Initially, the problem includes all nonnegativity constraints, balanced set constraints (Eqs 19 and 20), and generalized blossom inequalities (Eqs 20 and 21). The algorithm is preceded by generating additional balanced set and generalized blossom inequalities that are found to be violated. A number of Gomory cuts are also added to encourage integrality. If the solution is an integer and satisfies all

constraints, a minimum-cost Eulerian graph is identified and the procedure terminates. Otherwise, a branching process is to be initiated.

The Windy Chinese Postman Problem (WPP)

The WPP was first introduced by Minieka [18]. The feature of the WPP is that the cost of traversing an edge depends on the direction of travel: in one direction, the postman can walk with the wind resulting in a lower cost, whereas in the other direction, he must walk against the wind with more cost. It can be seen that UCPP, DCPM, and MCPM are special cases of WPP by using an appropriate definition of edge cost. For example, DCPM can be modeled by an infinite cost of travel on opposite directions of the arcs. An example of cost depending on the direction of travel is the different standby air fares between New York and London depending upon direction [18]. Previous studies [19] have shown that the WPP is an NP-hard problem. However, it has been proved that it is solvable in polynomial time if G is Eulerian [20], or if the two orientations (clockwise and counterclockwise) of every cycle have the same cost [21].

Let $\delta(i)$ be the set of edges incident to vertex v_i and $E(S)$ be the set of edges where $E(S) = (v_i, v_j) : v_i \in S, v_j \in V \setminus S$ and $S \subset V$. Furthermore, let x_{ij} be the number of times edge (v_i, v_j) is traversed from v_i to v_j . The WPP is represented as follows:

WPP Model 1

$$\text{Minimize} \quad \sum_{(v_i, v_j) \in A} (c_{ij} x_{ij} + c_{ji} x_{ji}) \quad (23)$$

$$\text{subject to} \quad x_{ij} + x_{ji} \geq 1 \quad ((v_i, v_j) \in A) \quad (24)$$

$$\sum_{(v_i, v_j) \in \delta(i)} (x_{ij} - x_{ji}) = 0 \quad (v_i \in V) \quad (25)$$

$$x_{ij}, x_{ji} \geq 0 \quad ((v_i, v_j) \in A) \quad (26)$$

$$x_{ij}, x_{ji} \text{ integer } ((v_i, v_j) \in A). \quad (27)$$

Let $P(G)$ be the convex hull of the feasible solutions to the integer program above, and let $Q(G)$ be the set of feasible solutions to its linear programming relaxation. Win [22] proved that every extreme point x of the polyhedron $Q(G)$ has components whose values are either $\frac{1}{2}$ or a nonnegative integer. Furthermore, $Q(G)$ is integral if and only if G is even. Let $S \subset V$ be such that $|E(S)|$ is odd. Grötschel and Win [23] showed that the following odd cut inequalities are valid for $P(G)$:

$$\sum_{(v_i, v_j) \in E(S)} (x_{ij} + x_{ji}) \geq |E(S)| + 1(S \subset V) \quad (28)$$

$$\sum_{v_i \in S, v_j \notin S} x_{ij} \geq \frac{1}{2}(|E(S)| + 1)(S \subset V) \quad (29)$$

$$\sum_{v_i \in S, v_j \notin S} x_{ji} \geq \frac{1}{2}(|E(S)| + 1)(S \subset V). \quad (30)$$

It is noticed that although there exists an exponential number of constraints in the above model and it has odd cut inequalities, it can still be solved in polynomial time by the Padberg and Rao procedure [24]. In general, the WPP has been solved by applying a cutting plane algorithm. For details, see Grötschel and Win [25], Win [20,22], and Gendreau *et al.* [26].

The Hierarchical Postman Problem (HPP)

If there is a predetermined order of how arcs need to be traversed, the WPP problem becomes the hierarchical postman problem (HPP). Take snow plowing operations, for example; emergency evacuation routes have higher priority and need to be serviced first. HPP can be defined on either a directed or an undirected graph, in which arcs or edges are partitioned into clusters $\{A_1, \dots, A_p\}$ with $p > 1$ such that precedence relations specify the order in which the clusters are to be traversed starting from and ending at the given depot. An example of the precedence relationship of arcs can be $A_1 \ll A_2 \ll \dots \ll A_p$, where $\ll$ represent a linear order.

Figure 4. Example graph to illustrate an HPP.

If the clusters obey a linear order, the precedence relationship is said to be completely defined. The objective of a HPP is to determine a least-cost tour of G starting from and ending at a given depot, and serving the arcs of each cluster in a manner where no edges in A_i can be served before the service of all edges in A_{i-1} is completed. For the graph depicted in Fig. 4, if vertex 1 is the depot, $A_1 = \{(1,2), (2,3), (2,4)\}$; $A_2 = \{(3,5), (5,6), (4,6), (4,7), (6,7)\}$; $A_3 = \{(2,8), (1,8)\}$ and $A_1 \ll A_2 \ll A_3$, then a HPP tour is $1 \rightarrow 2 \rightarrow 4 \rightarrow 2 \rightarrow 3 \rightarrow 5 \rightarrow 6 \rightarrow 7 \rightarrow 4 \rightarrow 6 \rightarrow 4 \rightarrow 2 \rightarrow 8 \rightarrow 1$. This variant of CPP has been applied in applications such as flame cutting [27], waste collection [28], and snow plowing operations in an urban or rural setting [29].

Consider subgraphs $G_i = (V_i, A_i)$ derived from graph G induced by the sets A_i ; the problem can be solved in polynomial time if each subgraph is connected and the precedence relation is completely defined [30]. On the other hand, when subgraphs are not connected or if the precedence relation is partial, the problem becomes NP-hard. Dror *et al.* [30] and G  linas [31] proved this by transformation of the HPP from the Hamiltonian path problem, which is known to be strongly NP-complete in both the undirected and directed cases.

Algorithms to solve HPP have been developed in the past years. G  linas [31] proposed an exact enumerative algorithm for an undirected HPP with given starting and ending vertices, and general precedence relation, in which all subgraphs are strongly connected. As opposed to linear precedence relation, which requires a unique partial

ordering relation between classes, general precedence relation imposes a weak partial ordering relation between classes. This is the situation where, for example, all arcs of A_{i-2} must be serviced before all arcs of A_i , but the arcs of A_{i-1} can be serviced either before or after some arcs of A_{i-2} and A_i . The algorithm to this problem was based on a dynamic program in which states correspond to the subgraphs that have been traversed. Dror [30] proposed an algorithm of $O(p|V|^5)$ if a graph is undirected and all subgraphs induced by A_i are connected. Korteweg and Volgenant [32] improved that result to $O(p|V|^4)$ by a layer algorithm for the same problem. Ghiani and Improta [33] proposed a lower computational complexity algorithm that solves the problem as matching on an auxiliary graph with $O(p|V|)$ computational time. Their algorithm is described below.

Ghiani and Improta's Algorithm.

- Step 0.* For each subgraph $G_i, i = 1, \dots, p$, determine V' and V'' , where V' is the subset of vertices of V_i incident to at least one edge in $\bigcup_{k=1}^{i-1} A_k$, and V'' is the subset of vertices of V_i incident to at least one edge in $\bigcup_{k=1}^{i-1} A_k \cup A_{i+1}$.
- Step 1.* Construct the auxiliary $(p+2)$ partite graph G^* as described in their paper.
- Step 2.* Find a minimum weight perfect matching on G^* .
- Step 3.* Introduce in G the shortest paths P corresponding to the solution found in step 2; let G' be the resulting graph.
- Step 4.* Determine an optimal tour on G' using the end-pairing algorithm.

OTHER VARIANTS OF THE CHINESE POSTMAN PROBLEM

There exist several variations of the CPP. The first related problem is called *open CPP*, where the starting vertex and ending vertex of the path do not have to be the same. Note that the sufficient and necessary condition for the existence of an Eulerian path on the undirected graph is that there are at most two odd-degree vertices. The open CPP is

also important in real-world applications. For example, finding the optimal test sequence for a website does not require returning to the homepage. In this case, the objective is to find the shortest length open Eulerian path, which is an open path that covers all the arcs on the graph.

If not all arcs of the graph are required to be covered, the problem is called *rural postman problem*. This problem comes from a rural area setting: there are a number of villages whose streets have to be serviced but the links between villages do not need to be serviced but may be used for traveling. For a recent survey of the applications and algorithms of rural postman problem (RPP), refer to Eiselt *et al.* [34].

Another problem related to the undirected CPP is attributed to Alpern and it is referred to as the utilitarian postman (UP) problem. The UP problem's objective is to minimize the mean time of delivery of mail to all customers. More generally, a UP path is the one that minimizes the expected time required to find a random (uniformly distributed) point on a network. The optimal UP path is one of the open Eulerian paths but may be longer than the CP path. Furthermore, unlike a CP tour on an undirected graph whose length is bounded by twice the length of the graph, a UP path may traverse an edge more than twice and therefore no similar bound exists for a general graph. Recent papers devoted to this problem include Refs 35 and 36.

Numerous covering problems associated with the undirected CPP and directed CPP have also attracted the attention of researchers. An m -vehicle version of the undirected CPP with the objective to minimize the length of the longest route was proposed by Frederickson *et al.* [37]. Cross [38] considered the problem of covering an undirected graph by undirected cycles where the total length of the cover is minimized. For the directed case, several covering criteria such as covering the graph with star trees, and simple paths or circuits have been studied [39].

FURTHER READING

Classical books for an introduction of the CPP from a graph theoretical perspective

include: Assad and Golden [40], Christofides [41], Evans and Minieka [42], and Fleischner [11]. More recently, a book on the subject was edited by Dror [43]. Eiselt *et al.* [3] proposed a detailed survey paper for the CPP. Furthermore, Laporte *et al.* [44] provides a list of 500 references on four classical routing problems, including the CPP.

For an overall understanding of exact algorithms for the undirected CPP, the directed CPP and the mixed CPP, refer to Edmonds and Johnson [10]. Heuristic algorithms to solve the mixed CPP can be found in Refs 16 and 37. More recent literature on WPP and HPP include Refs 29, 32, 45–48 and Frederickson [49].

CLASSIC FINANCIAL RISK MEASURES

ARCADY NOVOSYOLOV
Institute of Mathematics,
Siberian Federal
University, Krasnoyarsk,
Russia

The goal of risk management or decision making under risk is to provide appropriate decisions in situations when consequences of actions are vague and uncertain. An early mention of a risk management technique is from Daniel de Foe: it may be found in his famous “Robinson Crusoe” [1]. During the first rain storm in the desert island, a sudden flash of lightning had struck Robinson Crusoe with a thought that all his powder might be destroyed in one blast. So after the storm, he separated the powder in not less than a hundred parcels. This is an early example of diversification, which is one of the risk management techniques.

Measurement is a process of ordering, if not quantifying. In the early twentieth century, there was some debate as to whether all risks are amenable to ordering, quantification or measurement. See, for example, Refs 2, 3 or for more modern treatment, Ref. 4. Any discussion of risk measurement should be understood in the context of that caveat.

For the sake of simplicity, we will confine ourselves to considering only a single period setting here, so that decision is made at present time t_0 , and consequences of the decision are to be exposed at some future time t_1 . Dynamic risk measures have attracted significant attention during the last decade, so we classify them as contemporary rather than classic. Thus, the consequences of a decision d are described by a random variable $X = X_d$, its values are interpreted as possible profit/loss values. In some cases it is more convenient to use cumulative distribution functions $F = F_d$ instead. Recall that cumulative distribution function F of a random

variable X is defined over real numbers $\mathbf{R}$ as follows:

$$F(t) = \mathbf{P}(X \leq t), \quad t \in \mathbf{R}.$$

RISK MEASURES VERSUS RISKINESS MEASURES

Unfortunately, there is an ambiguity of terminology in the field of risk measurement. The term “risk measure” is sometimes used to name functionals that measure risk *per se*. These functionals are expected to take positive values for risky actions (consequences), and zero value for risk-free actions (consequences); they never take negative values. Such risk measures take only risk into account and ignore benefits obtained in exchange for the risk. They should take larger values for riskier decisions (the more—the riskier). Variance is a typical example of risk measure of this first kind.

Another usage of the term “risk measure” assumes these functionals take into account not only risk, but also benefits and all other relevant information about consequences of decisions. These functionals take larger values for better decisions (the more—the better), so they represent preferences over actions (consequences). The functionals can usually take arbitrary real values, both positive and negative; zero value of such functionals does not have any specific meaning. These functionals may be also called *decision criteria*, since making decisions may be formalized as maximization of such functionals. Certainty equivalent is a typical measure of this second kind. Note that riskiness measures and decision criteria are often, though not always, related through expectation $\mathbf{E}X$ of risk X by

$$\begin{aligned} \text{riskiness measure}(X) &= \text{decision tool}(X) \\ &\quad - \mathbf{E}X. \end{aligned}$$

Though using the term “risk measure” for the functionals of the first kind is more intuitive

and attractive, it is more often used in the literature for the functionals of the second kind. Well-known examples are expected utility functionals briefly considered in the present article and also presented in a separate article, and coherent risk measures considered in a separate article.

RISK

Financial risk in a one-period setting is often thought of as uncertainty in a financial result (gain or loss). For purposes of measurement, this is modeled with a random variable. In a simple case, the size of loss may be known in advance and fixed, only probability of loss may vary; the loss probability serves as a risk measure of the first kind:

$$\text{amount of risk} = \text{probability of loss.}$$

Note that negative of this functional may be treated as a risk measure of the second kind. If the loss size may vary too, the amount of risk is often measured by

$$\begin{aligned} \text{amount of risk} &= (\text{value of loss}) \\ &\quad \times (\text{probability of loss}) \end{aligned}$$

Denoting v the value of loss and p its probability, we can describe the loss as a random variable X with the following distribution

$$X: \begin{array}{ll} \text{Value} & 0 \quad v \\ \text{Probability} & 1-p \quad p \end{array}$$

In this case, risk might be measured as $f(X) = vp$, the expected value $\mathbf{E}X$ of the loss random variable X . This value may be regarded as a risk measure of the first kind and again, its negative may be considered as a risk measure of the second kind. Such a duality is possible due to a narrow set of allowed risks.

More generally, profit/loss distribution may be represented by a discrete random variable in the form

$$X: \begin{array}{lllll} \text{Value} & x_1 & x_2 & \dots & x_n \\ \text{Probability} & p_1 & p_2 & \dots & p_n \end{array},$$

and the risk of X may be measured by

$$f(X) = \mathbf{E}X = \sum_{i=1}^n X_i p_i.$$

This value $f(X)$ may be regarded as a proxy for the certainty equivalent of X , or the price at which the uncertain loss X may be sold and bought in a financial market; for example, as an insurance policy. When all expenses are included in the values of X , this functional $f(\cdot)$ may be used as a (very crude) decision criterion, that is, the risk measure of the second kind.

ST. PETERSBURG PARADOX

In 1738 Daniel Bernoulli published the paper [5] where expectation was shown to be not appropriate as a risk measure. This view was supported by presenting a game with infinite expected gain, so a mean-driven person would be willing to pay any amount of money to enter the game, while real persons would hardly behave that way, thus giving rise to a paradox.

The game is played as follows: A fair coin is tossed till the first appearance of heads. If the first appearance occurs at the n -th toss, then the gain is equal to 2^n dollars. Since the probability of the first appearance of heads at the n -th toss is 2^{-n} , we have the following gain description of the game:

	Toss of heads appearance	1	2	...	n	...
X :	Value of gain	2	4	...	2^n	...
	Probability of the gain	1/2	1/4	...	2^{-n}	...

so the mean gain is indeed infinite:

$$\mathbf{E}X = \sum_{n=1}^{\infty} 2^n 2^{-n} = 1 + 1 + \dots = \infty.$$

Infiniteness of expectation means that though gain in each game is finite, the average gain in a long series of games tend to increase without bound, although it increases very slowly. Figure 1 illustrates the effect for a series of 1000 games. The data for the graph has been prepared as follows: Consider a sequence of 1000 games, denote X_k the gain

Figure 1. Average gain in m consecutive games, $m = 1, 2, \dots, 1000$.

in the game $k, k = 1, \dots, 1000$, and denote S_m the average gain after m games:

$$S_m = \frac{1}{m} \sum_{k=1}^m X_k, \quad m = 1, 2, \dots, 1000.$$

From a strict probabilistic point of view, S_m is a random process, and Fig. 1 depicts a sample path of that process.

To overcome the paradox, Bernoulli suggested using the mean logarithm of a random variable instead of its expectation as a decision criterion (risk measure), that is, calculating

$$f(X) = \mathbf{E} \log X.$$

Using logarithm base 2 provides for our game

$$\begin{aligned} f(X) &= \mathbf{E} \log_2 X = \sum_{n=1}^{\infty} 2^{-n} \log_2 2^n \\ &= \sum_{n=1}^{\infty} n 2^{-n} = 2. \end{aligned}$$

According to Bernoulli's suggestion, fair price Q for the game is equal to the monetary value, which has the logarithm equal to $f(x) = 2$, that is, $\log_2 Q = 2$, which gives $Q = 4$.

EXPECTED UTILITY

Logarithms are used to calculate utility of wealth in the above consideration, which is why it is called *utility function* in this framework. Using other utility functions U , instead of the logarithms, provides the more general expected utility principle. According to this principle, given a utility function U , one should calculate expected utility $f(X) = \mathbf{E}U(X)$ of the game X and then find the fair price Q for the game X so that $U(Q) = \mathbf{E}U(X)$. In other words, utility of Q should be equal to the expected utility of X .

Typically the utility function is chosen to be strictly increasing, in which case the inverse function U^{-1} exists, so the fair price (certainty equivalent) may be also calculated directly by

Figure 2. Increasing concave utility function.

$$Q = U^{-1}(\mathbf{E}U(X)).$$

If additionally U is concave (sometimes such functions are also called *convex upwards*), it is said to exhibit risk aversion. Indeed, in this case a certain amount has greater or equal utility than any risky amount with the same mean value. Figure 2 presents an example of typical increasing concave utility function and illustrates the risk aversion concept. Here the utility function takes the form

$$U(x) = 1 - \exp(-x).$$

Consider the risk (random gain) described by the table

X :	Value	-1	1
	Probability	$\frac{1}{2}$	$\frac{1}{2}$

Since $U(-1) = -1.718$ and $U(1) = 0.632$, the expected utility of the risk X equals

$$\mathbf{E}U(X) = \frac{1}{2}U(-1) + \frac{1}{2}U(1) = -0.543.$$

Next, $\mathbf{E}U(X)$ is less than $U(\mathbf{E}X) = U(0) = 0$, so the expected utility principle declares the

risk X less preferable than its expected value $\mathbf{E}X$. Moreover, the inverse utility function U^{-1} is uniquely defined:

$$U^{-1}(z) = -\ln(1 - z), \quad z \in (-\infty, 1);$$

thus, we can calculate the certainty equivalent of the risk X as follows:

$$Q = U^{-1}(\mathbf{E}U(X)) = -\ln(1 + 0.543) = -0.434.$$

The points $(-1, U(-1))$ and $(1, U(1))$ are marked in Fig. 2 by squares; the triangle represents the utility of risk point $(\mathbf{E}X, \mathbf{E}U(X))$, and the diagonal cross marks the certainty equivalent of the risk X .

The expected utility principle was supplied with a solid ground in the seminal book by von Neumann and Morgenstern [6], where they built an axiomatic theory of expected utility. In particular, they showed that if preference over probability distributions is linear in some specific sense, then it may be represented by an expected utility functional. To be more precise, for two risks X and Y denote $X \preceq Y$ the fact that Y is at least as preferred as X . If the preference relation $\preceq$ possesses

the linearity property mentioned above, then there exists a utility function U (unique in some sense) such that $\mathbf{E}U(X) \leq \mathbf{E}U(Y)$ if and only if $X \preceq Y$.

Linearity of the preference relation generated by an expected utility functional may be illustrated by a simple example. Consider the set of risks such that each risk can take only three values 1, 2, 3 with corresponding probabilities p_1, p_2, p_3 . Then distribution of any such risk X may be described by only two parameters p_1, p_2 such that $p_1 \geq 0, p_2 \geq 0$ and $p_1 + p_2 \leq 1$. The third probability is clearly equal to $p_3 = 1 - p_1 - p_2$. The set of all admissible parameters p_1, p_2 is represented by a shaded triangle on a plane (Fig. 3). We say that two risks X, Y are equivalent and denote the fact by $X \sim Y$, if $X \preceq Y$ and $X \succeq Y$. An equivalence class K contains only equivalent risks, so that $X, Y \in K$ if and only if $X \sim Y$. Alternatively, equivalence classes may be described by the expected utility condition: $X, Y \in K$ if and only if

$$\mathbf{E}U(X) = \mathbf{E}U(Y) = \alpha_K.$$

Different values of α_K correspond to different equivalence classes. Each dashed line in Fig. 3 represents an equivalent class. Equivalence classes are segments of parallel straight lines; this property is characteristic

Figure 3. Equivalence classes of a linear preference relation.

for the expected utility principle. This is why we call the corresponding preference relations linear.

MARKOWITZ MEAN-VARIANCE APPROACH

In 1952 Harry Markowitz in his seminal paper [7] introduced the mean-variance approach to portfolio selection. For simplicity we will start with the case of two assets. Let $X = (X_1, X_2)'$ be a random vector, whose component X_i represents return of asset i over a fixed horizon $i = 1, 2$; prime denotes transpose vector. Given weight w , a portfolio containing a portion w of the first asset and a portion $1 - w$ of the second asset, provides a return $P_w = wX_1 + (1 - w)X_2$ over the same horizon. The random variable P_w has expectation and variance

$$\begin{aligned} \mathbf{E}P_w &= w\mathbf{E}X_1 + (1 - w)\mathbf{E}X_2, \\ \sigma^2(P_w) &= w^2\sigma^2(X_1) + 2w(1 - w)r\sigma(X_1)\sigma(X_2) \\ &\quad + (1 - w)^2\sigma^2(X_2), \end{aligned}$$

where r denotes correlation of X_1 and X_2 . The expected return $\mathbf{E}P_w$ may informally be called *return*, and the variance $\sigma^2(P_w)$ is often treated as a proxy for the risk of the portfolio P_w . This is why the approach is often called *risk-return approach*. The essence of this approach is minimizing risk given a fixed return value M or, equivalently, solving the following optimization problem:

$$\sigma^2(P_w) \rightarrow \min_w, \quad (1)$$

$$\mathbf{E}P_w = M. \quad (2)$$

If short-selling is prohibited or impossible, then additional constraint

$$0 \leq w \leq 1 \quad (3)$$

is also included into the optimization problem.

The parameter M describes risk appetite of a decision maker. The more risky decision maker would set larger value of M and get a more risky solution of the Markowitz optimization problem.

Figure 4. Graphs of risk of two-asset portfolios with different asset correlation.

Note also that along with the problems (1)–(3), Markowitz in Ref. 7 had considered the equivalent problem of maximizing expected return given a level of risk, namely,

$$\begin{aligned} \mathbf{E}P_w &\rightarrow \max_w, \\ \sigma^2(P_w) &= \Sigma^2 \end{aligned}$$

with the additional constraint (3) if short-selling is prohibited or impossible.

Let us illustrate the diversification effect which might be obtained using portfolio selection. To keep things simple, assume that asset returns are equal, $\mathbf{E}X_1 = \mathbf{E}X_2 = R$, and asset variances are also equal, $\sigma^2(X_1) = \sigma^2(X_2) = D^2$. In this case the constraint $\mathbf{E}P_w = M$ does not make sense, since always $\mathbf{E}P_w = R$, so the Markowitz problem reduces to just minimizing risk, which in this case equals

$$\begin{aligned} \sigma^2(P_w) &= D^2 (w^2 + 2w(1-w)r + (1-w)^2) \\ &= D^2 (2w^2(1-r) - 2w(1-r) + 1). \end{aligned}$$

If $r = 1$, then the portfolio risk is always equal to D^2 and there is no diversification in case of perfectly correlated assets. If $-1 \leq r < 1$,

then the minimum risk is clearly attained at $w = 1/2$, and is equal to

$$D^2 \frac{1+r}{2}.$$

We see that the closer r value to -1 , the stronger the diversification. In the ideal case $r = -1$, we obtain zero risk. Figure 4 illustrates this example by presenting graphs of risk vs w for values of $r = -1; -0.5; 0; 0.5; 1$.

The general case of n assets is quite similar. Denote $X = (X_1, \dots, X_n)'$ the random vector with components describing returns of assets on a given horizon and $w = (w_1, \dots, w_n)'$ the vector of weights. Then return of a portfolio has the form

$$P_w = w'X = \sum_{i=1}^n w_i X_i$$

and its expected return and risk are

$$\begin{aligned} \mathbf{E}P_w &= w'm = \sum_{i=1}^n w_i m_i, \\ \sigma^2(P_w) &= w'Vw = \sum_{i,j=1}^n v_{ij} w_i w_j, \end{aligned}$$

where $m = (m_1, \dots, m_n)'$ with $m_i = \mathbf{E}X_i$, $i = 1, \dots, n$ is the vector of expected returns, and

$V = (v_{ij})$ with $v_{ij} = \text{Cov}(X_i, X_j), i, j = 1, \dots, n$ is a variance–covariance matrix. The Markowitz problem still has the form of Equations (1), (2) with the additional constraint

$$w_1 + \dots + w_n = 1, \quad (4)$$

and more additional constraints in case of impossibility of short trades:

$$w_1 \geq 0, \dots, w_n \geq 0.$$

In case of asymmetric distributions, using variance $\sigma^2(P_w) = \mathbf{E}(P_w - \mathbf{E}P_w)^2$ as a riskiness measure may not be natural, because it imposes equal penalty to both downside and upside deviations from the mean. In such circumstances many authors, including Markowitz, suggest using downside measures like semivariance, which is defined as conditional expectation of the form

$$\sigma_-^2(P_w) = \mathbf{E} \left((P_w - \mathbf{E}P_w)^2 \mid P_w \leq \mathbf{E}P_w \right).$$

MARKOWITZ RISK MEASURES

It turns out that solving a Markowitz problem (Eqs 1, 2, and 4) is equivalent to solving the problem

$$\mathbf{E}P_w - \gamma \sigma^2(P_w) \rightarrow \max_w \quad (5)$$

with constraint (4), where $\gamma > 0$ is uniquely defined by the parameter M in Equation (2). The parameter γ describes the risk aversion of a decision maker; smaller values correspond to more risky decision makers. This equivalence invokes using the functional

$$f(X) = \mathbf{E}X - \gamma \sigma^2(X) \quad (6)$$

as a decision criterion, or risk measure of the second kind. Note that the Markowitz problem (Eqs 1 and 2) allows equivalent statement with portfolio standard deviation $\sigma(P_w)$ as a goal function instead of the variance as in Equation (1). This observation leads to another risk measure of the second kind, related to the Markowitz problem. Fix $\alpha > 0$ and consider a functional

$$f(X) = \mathbf{E}X - \alpha \sigma(X).$$

One can easily see that this functional is

- positive homogeneous, that is, $f(tX) = tf(X), t \geq 0$;
- superadditive, that is, $f(X + Y) \geq f(X) + f(Y)$;
- translation invariant, that is, $f(X + a) = f(X) + a$ for real a .

However it is not a monotone, that is for risks X, Y such that $X \leq Y$; both inequalities $f(X) > f(Y)$ and $f(X) < f(Y)$ are possible. To show this, consider a degenerate risk X with $\mathbf{P}(X = 0) = 1$ and a family of Bernoulli risks Y_p with

$$\mathbf{P}(Y_p = 1) = p, \mathbf{P}(Y_p = 0) = 1 - p,$$

where p is a parameter. We have $f(X) = 0$ and $Y_p \geq X$, however,

$$f(Y_p) = p - \alpha \sqrt{p(1-p)}$$

may take both positive and negative values. Indeed,

$$f(Y_p) < 0 \text{ for } 0 < p < \frac{\alpha^2}{1 + \alpha^2}, \quad f(Y_p) > 0 \text{ for } \frac{\alpha^2}{1 + \alpha^2} < p \leq 1,$$

see illustration in Fig. 5 for $\alpha = 0.5$. The properties of positive homogeneity, superadditivity, translation invariance, and monotonicity are closely related to the so-called coherent risk measures which are covered in a separate article.

VALUE-AT-RISK

Value-at-risk (VaR) was introduced into financial applications in the early 1990s by a RiskMetrics technical document, the latest version of which is available in Ref. 8. In a nutshell, VaR means the following: suppose someone tells you that a given portfolio will lose \$10,000 one day in ten. In the language of VaR, he/she is telling you that the portfolio has a one-day 90% VaR of \$10,000—that nine days out of ten, it will lose less than \$10,000 or even gain something.

Figure 5. Markowitz functional for a family of Bernoulli risks.

More formally, VaR is a number such that with a given probability, loss over a given horizon will not exceed that number. Fix a horizon, say one day, a confidence level or probability, say 90%, and consider a profit/loss distribution with the density shown in Fig. 6. The one-day 90% VaR is shown in the figure by the square mark. In other words, 90% of the distribution probability belongs to the best side of the distribution, while the remaining 10% belongs to the worst side.

Calculating VaR is largely a process of somehow constructing a profit/loss distribution such as that of Fig. 6 and then taking the desired quantile. Inputs must provide information about both, the volatility (uncertainty) in market prices, interest rates or other market variables, as well as information about the portfolio's exposures to those market variables. For the former, historical values for the market variables are used. The latter is obtained from the portfolio's holdings. See Ref. 9 for a more detailed discussion.

Let us describe a parametric method for one-day VaR calculation in more detail. It usually starts with a factor model

$$A = LB + Z, \quad (7)$$

where B stands for an $n \times 1$ vector of one-day factor returns, which is supposed to have a joint normal distribution with zero mean and variance-covariance matrix C_B , $m \times n$ matrix L stands for loadings, Z denotes normal random vector with zero mean and diagonal variance-covariance matrix C_Z , and is interpreted as asset-specific variance source (noise). Here, A denotes $m \times 1$ vector of asset returns. Factor and noise are assumed to be mutually independent. From factor model assumptions it follows that A has a joint normal distribution with zero mean and variance-covariance matrix $C_A = LC_B L' + C_Z$.

Now consider an $m \times 1$ vector w of weights, and compose a portfolio of assets with these weights; its return takes the form $P_w = w'A$. This is clearly a normal random variable with zero mean and variance $\sigma^2(P_w) = w'C_A w$. Thus, its α -quantile equals $q_\alpha \sqrt{w'C_A w}$, where q_α denotes the α -quantile of the standard normal distribution, for example $q_{0.9} = 1.2816$. Finally, if the current portfolio value equals S_0 , then its one-day α -VaR equals $S_0 q_\alpha \sqrt{w'C_A w}$.

VaR is a rather simple method of risk measurement and communication. It has a number of disadvantages though, especially when

Figure 6. One-day 90% VaR illustration.

normality assumption cannot be justified. First, VaR tells us nothing about tail behavior of the distribution of interest, in particular, it cannot catch the so-called “fat tails” or “heavy tails” [10]. Second, in general, VaR is not a subadditive functional, so it may fail to support decision leading to diversification [2,11]. These features force both researchers and practitioners to look for advanced risk measures. Representatives of those, coherent risk measures, are considered in a separate article.

FURTHER READING

For a general discussion of risk, see Refs 2–4. For deeper understanding of expected utility theory, preferences over distributions, and basics of decision making under risk, the classic monograph [6] is a must-read. Development of the Markowitz mean–variance approach may be found in the book [12], and also in the publications of his colleagues

[13,14]. For calculation and interpretation VaR, see Ref. 9. An interesting class of risk measures, the so-called risk-value functionals, are presented in Ref. 15 and other papers of these authors. A coherent modification of VaR, the conditional VaR, was introduced in Ref. 16. There is also a vast literature on dynamic risk measurement [17]. Some paradoxes of choice among random alternatives are discussed in Ref. 18.

CLIQUE RELAXATIONS

BENJAMIN MCCLOSKEY
Nature Source Genetics,
Ithaca, New York

INTRODUCTION

Researchers have historically studied the clique concept from a variety of perspectives. For example, cliques arise in extremal graph theory [1], complexity theory [2,3], random graph theory [4,5], and perfect graph theory [6–8]. In addition, cliques provide the applied mathematician with a natural framework for modeling and detecting relationships among elements of a system [9–11].

In practice, the precise definition of a clique can be overly restrictive [12], thus motivating the study of clique relaxations. This article discusses various ways to relax the clique concept. The remainder of this section contains a brief survey of applications from the field of social network analysis to motivate the more precise definitions and concepts found in later sections. While applications serve to motivate the present discussion, it should be noted that the theoretical aspects of clique relaxations are an active area of research as well [13–15].

Consider the example of a social network $G = (V, E)$, where G is finite, simple, and undirected. The vertex set V represents people (or *actors*). The edge set E represents mutual relationships between pairs of actors. As the following examples show, social networks have become a popular topic.

For instance, suppose the edges in a social network denote physical contact between people. Health officials use these *contact networks* to study the spread of infectious diseases [16,17]. The rate of disease transmission naturally accelerates in regions with high adjacency levels, and the identification of dense subnetworks can help officials understand how certain actions, such as

closing schools, might affect the rate of transmission [18].

Now suppose the social network edges denote mutual friendship. Advertisers have long had an interest in exploiting friendship networks for marketing purposes [19–21], and research has found a significant and positive impact of friends' purchases on the purchase probability of an individual [22]. In particular, analysts study how the influence of certain actors can propagate throughout the network [23,24]. This spread of influence depends on the structure of the network and is greatly facilitated by the presence of dense subnetworks.

As a final example, suppose the network edges represent collaboration between researchers. These *collaboration networks* have been constructed for mathematicians and computational geometers [25,26]. Collaboration networks are used to determine collaborative distance between researchers, a notion popularized by the concept of Erdős numbers [27].

Each of these applications involves the search for subsets potentially modeled as cliques, but there are other options. The following section introduces alternatives to the clique. The section titled “Combinatorial Algorithms” discusses algorithms for finding certain clique relaxations, and the section titled “Theoretical Results” contains some results related to these objects.

RELAXING CLIQUES

Cliques consist of pairwise adjacent vertices. This section discusses examples of clique relaxations. But first, recall the following standard graph-theoretic terminology [28]. Let $N(v) = \{u \in V : vu \in E\}$ and $\deg(v) = |N(v)|$. Let $d_G(v, u)$ be the length of a shortest vu -path in G , and let $G[S]$ be the subgraph induced by $S \subseteq V$. The diameter of a graph is equal to $\max_{u,v \in V} d_G(v, u)$.

Some possibilities for relaxing cliques include imposing a bound on adjacency level,

graph-based distance, or edge-to-vertex ratio. Notice that cliques have a high adjacency level, small diameter, and high edge-to-vertex ratio. Let $\lambda \in [0, 1]$ and $k \geq 1$ be a fixed integer.

Definition 1 [29]. A k -plex S satisfies $|S \cap N(v)| \geq |S| - k$ for all $v \in S$.

k -plexes are degree-based clique relaxations. The degree requirement must hold at every vertex, so k -plexes tend to be highly structured. Notice also that k -plexes form a superset of cliques (i.e., cliques are 1-plexes). The section titled “Combinatorial Algorithms” contains a maximum k -plex algorithm, and the section titled “Theoretical Results” discusses some aspects of the k -plex polytope.

Definition 2 [30]. A k -core satisfies $|S \cap N(v)| \geq k$ for all $v \in S$.

k -cores relax the degree requirement of cliques in a considerably less stringent way than k -plexes. In particular, the k -core degree bound is independent of S . This independence allows the structure of k -cores to differ greatly from k -plexes and leads to a simple algorithm for finding maximum k -cores discussed in the section titled “Combinatorial Algorithms.”

The k -core and k -plex concepts have a superficial relationship in that any k -plex S is also a $(|S| - k)$ -core. Conversely, however, a maximum $(|S| - k)$ -core could be much larger than $|S|$ and need not be a k -plex. Therefore, this fact has no algorithmic consequences.

Definition 3 [31]. A k -club satisfies $d_{G[S]}(v, u) \leq k$ for all $u, v \in S$.

k -clubs are an example of distance-based clique relaxations. k -clubs have the interesting property that testing their maximality is NP-complete [13]. The section titled “Combinatorial Algorithms” describes a maximum k -club algorithm. The section titled “Combinatorial Algorithms” discusses some further properties of k -clubs.

Definition 4 [32]. A k -clique satisfies $d_G(v, u) \leq k$ for all $u, v \in S$.

k -cliques offer a second example of distance-based clique relaxations. k -cliques and k -clubs have much in common; the main difference being that the distance measurements used to define k -cliques do not depend on the subgraph $G[S]$. Notice that k -clubs form a proper subset of k -cliques.

Definition 5 [33]. A λ -quasi-clique satisfies $|E(G[S])| \geq \lambda \frac{|S|(|S|-1)}{2}$.

Quasi-cliques have received other definitions in the literature [34]. Here they are defined to obtain high edge density, but note that the definition fails to ensure highly structured subsets. Indeed, a quasi-clique can have vertices with very low degree. On the other hand, density does imply connectivity. More precisely, a classic theorem of Mader states that every graph with edge density at least $3k$ and sufficiently many vertices contains a k -connected subgraph with at least r vertices or r pairwise disjoint k -connected subgraphs [35].

The examples in this section offer various approaches to relaxing the clique concept. A more thorough discussion of these objects can be found in Ref. 12. The following section deals with algorithms for finding clique relaxations.

COMBINATORIAL ALGORITHMS

This section discusses combinatorial algorithms for finding the clique relaxations discussed above. Finding a maximum k -core is especially easy. Sequentially deleting all vertices of degree at most $k - 1$ results in either a maximum k -core if one exists or the empty graph [12]. The difficulty of optimizing for quasi-clique varies. On the one hand, finding a subgraph with maximum edge density can be solved in polynomial time through a series of min cut calculations [36,37]. On the other hand, given $k \geq 1$, the problem of finding a subgraph on k vertices with the maximum number of edges is NP-complete [38].

Combinatorial branch and bound algorithms offer a standard approach to the NP-complete problems of finding maximum k -plexes, k -cliques, or k -clubs. Maximum clique has been extensively studied [39–42], so it is natural to start by adapting a well-known clique algorithm [10]. Consider the recursive clique algorithm in Algorithm 1.

Algorithm 1. Clique algorithm

```

function Clique( $U, K$ )
1.  if  $U = \emptyset$ 
2.      if  $|K| > \text{max}$  and  $K$  is feasible
3.           $\text{max} = |K|$ 
4.      end
5.      return
6.  end
7.  while  $U \neq \emptyset$ 
8.      if  $|K| + b(U) \leq \text{max}$ 
9.          return
10.  end
11.  Choose  $v \in U$ 
12.   $U = U \setminus \{v\}$ 
13.  Clique( $U \cap N(v), K \cup \{v\}$ )
14. end
15. return
    
```

For the initial call, set $U = V(G)$ and $K = \emptyset$. Refer to K as the current set and to U as the candidate set. The candidate set contains elements that can extend the current set. The function b in line 8 produces an upper bound on $\max_{S \subseteq U} |S|$ such that $K \cup S$ is a clique. A typical algorithm would use graph coloring for this bound. Line 13 redefines the candidate set as a consequence of adding v to the current set. Note that lines 8 and 13 are the only instructions specific to cliques. Consequently, adapting this algorithm amounts to redefining b and determining how the candidate set changes with respect to changes in the current set.

For k -plex and k -clique, adapting the candidate set is straightforward. Specifically, $K \cup \{u\}$ must be a feasible solution for all $u \in U$. This follows from the fact that k -plexes and k -cliques are closed under set inclusion. More precisely, if there exists a subset $S \subseteq U$ such that S extends K , then all subsets of $K \cup S$ are feasible. In particular, $K \cup \{u\}$ is feasible for all $u \in S$. Notice also that, when applied to k -plexes or k -cliques, the algorithm maintains the feasibility of the current set K .

To adapt the bound function b for k -plex and k -clique, simply partition the candidate set in a way that limits the intersection of a feasible solution with each partition class. Then the number of partition classes produces a bound on the amount that U can extend K . Co- k -plex colorings [14] and distance k -colorings [13] are known partitions for bounding k -plex and k -clique candidate sets, respectively.

In contrast, k -clubs are not closed under set inclusion, and testing k -club maximality is NP-complete [13]. Therefore, constructing a candidate set in terms of elements that extend a k -club must be NP-complete as well. One way to circumvent this computationally intractable subproblem is to relax the algorithm’s feasibility invariant. In other words, allow the current set to become infeasible at certain nodes in the branch and bound tree. In practice, one can define the k -club current set, candidate set, and bound function as in the k -clique algorithm described above [13]. However, it is important that the variable max be set only by feasible k -clubs. The validity of this approach follows from the fact that all k -clubs are also k -cliques, so the algorithm never prunes feasible k -clubs with the potential to improve the incumbent.

A second approach for designing combinatorial algorithms also has its origin in the clique literature [40]. The idea is to reverse the algorithm in Algorithm 1. In the context of cliques, the algorithm iteratively finds a maximum clique in $G[\{v_1\}]$, $G[\{v_1, v_2\}]$, $\dots$, and G . The algorithm maintains the invariant that the candidate set is contained in a graph for which the size of a maximum clique is known. This invariant leads to an effective bounding function.

It is easy to see that such an algorithm generalizes to find a maximum independent set in any independence system, so k -plex and k -clique algorithms follow immediately [14,43]. Using the same algorithmic tricks described above, one could devise a similar approach to find maximum k -clubs as well. The algorithm would essentially run the k -clique version to establish bounds, but it would not advance from $G[\{v_1, v_2, \dots, v_i\}]$ to $G[\{v_1, v_2, \dots, v_{i+1}\}]$ before eliminating the possibility of finding a new incumbent k -club.

through further branch and bound. This is an interesting area for future research.

This section focuses on combinatorial algorithms for finding clique relaxations. However, researchers have studied other approaches for finding k -plexes, k -cliques, and k -clubs including integer programming [12,44], fixed-parameter algorithms [15], and heuristics [45–48].

THEORETICAL RESULTS

This section briefly discusses some theoretical results related to k -plexes, k -clubs, and k -cliques. The content is limited to complexity and polyhedral results.

Concerning complexity, maximum k -club, k -clique, and k -plex are all NP-complete. This follows directly from the fact that for $k = 1$, these problems reduce to maximum clique. Moreover, k -club remains NP-complete even on graphs with diameter at most $k + 1$ [49] and has the additional property that testing maximality is NP-complete [13]. It is also difficult to test for a gap between k -clubs and $k + 1$ -clubs. The same result holds for k -cliques. Let $\bar{\omega}_k(G)$ and $\tilde{\omega}_k(G)$ denote the largest k -club and k -clique in G .

Theorem 1 [50]. *Given $k < l$, it is NP-hard to test if $\bar{\omega}_k(G) = \bar{\omega}_l(G)$ or $\tilde{\omega}_k(G) = \tilde{\omega}_l(G)$.*

One can represent the maximum k -clique problem as the maximum clique problem on the related power graph [44]. Given $G = (V, E)$, let $F = \{u, v \in V : d_G(u, v) \leq k\}$ and $G^k = (V, F)$. Clearly, a clique in G^k is a k -clique in G . Therefore, bounding the size of cliques in G^k is equivalent to bounding the size of k -cliques in G . Note also that this relationship leads to bounds on $\bar{\omega}_k(G)$ since $\bar{\omega}_k(G) \leq \tilde{\omega}_k(G)$. These ideas are further developed in Ref. 13.

Another line of research seeks to bound the size of the search tree. This approach typically relies on data reduction techniques to reduce the complexity of a problem instance. Applying these techniques can lead to results such as the following.

Theorem 2 [15]. *The search tree for testing the existence of a cardinality m*

2-plex can be bounded to have $\mathcal{O}(2.31^m)$ nodes, and maximum 2-plex can be solved in $\mathcal{O}(k^{5/2}2.31^k + kn)$ time.

Integer programming techniques offer another approach to finding maximum k -plexes, k -cliques, and k -clubs. These formulations also induce an associated class of polyhedra. Given $u, v \in V$, let C_{uv}^k be the set of all $u-v$ paths P in G such that $|E(P)| \leq k$. Let C be the set of all paths in G and V_t be the vertex set of path t . Maximum k -club can be formulated as follows [44]:

$$\begin{aligned} \text{Max.} \quad & \sum_{v \in V} x_v \\ \text{s.t.} \quad & x_v + x_u - \sum_{t \in C_{uv}^k} y_t \leq 1 \quad \forall u, v \in V \\ & y_t - x_v \leq 0 \quad \forall t \in C; v \in V_t \\ & x_v, y_t \in \{0, 1\} \quad \forall v \in V; t \in C. \end{aligned}$$

Notice that the first constraint reduces to $x_v + x_u \leq 1$ whenever $C_{uv}^k = \emptyset$. The y variables prevent the consideration of any path not entirely included in the induced subgraph. For the k -clique problem, one can eliminate the y variables to obtain the following formulation [49]:

$$\begin{aligned} \text{Max.} \quad & \sum_{v \in V} x_v \\ \text{s.t.} \quad & x_v + x_u \leq 1 \quad \forall u, v \in V \text{ s.t. } C_{uv}^k = \emptyset \\ & x_v \in \{0, 1\} \quad \forall v \in V. \end{aligned}$$

The k -club formulation was introduced in Ref. 44. The k -clique formulation and a polyhedral analysis of the 2-club polytope were given in Ref. 49. The facial structure of both the k -clique and k -club polytopes offer an interesting topic for future research. Let $N[v] = \{u \in V : uv \in E\} \cup \{v\}$ and $\bar{N}(v) = V \setminus N[v]$. Maximum k -plex can be formulated as follows [12]:

$$\text{Max.} \quad \sum_{v \in V} x_v$$

Figure 1. Minimal 2-claws.

$$\begin{aligned} \text{s.t.} \quad & \sum_{u \in \bar{N}(v)} x_u \leq (k-1)x_v + |\bar{N}(v)|(1-x_v) \\ & \forall v \in V \\ & x_v \in \{0, 1\} \quad \forall v \in V. \end{aligned}$$

The facial structure of this polytope was first examined in Ref. 12, and a further investigation was reported in Ref. 14. A successful approach to analyzing this polytope involves generalizing well-known inequalities, such as cycles and webs [51], from the related stable set polytope. Finding further inequalities is an interesting area for future work.

One can also use 2-plexes to characterize a class of integral polytopes. Given G , define the 2-plex clutter matrix A so that the rows of A are the incidence vectors of all maximal 2-plexes in G . Define the minimal 2-claws to be the graphs shown in Fig. 1.

Theorem 3 [14]. *If A is a 2-plex clutter matrix for G , then $\{x \in \mathbf{R}_+^n \mid Ax \leq 2, x \leq 1\}$ is integral if and only if G contains no minimal induced 2-claw or induced cycle C^n where $n \not\equiv 0 \pmod{3}$.*

Since it describes integral polyhedra in terms of excluding induced subgraphs, this result can be viewed as a polyhedral 2-plex analogue to graph perfection. However, combinatorial and polyhedral notions of 2-plex perfection do not seem to coincide. This theorem also implies the existence of a polynomial time algorithm for testing the integrality of polytopes defined by 2-plex clutter matrices. It is unknown if one can test whether A is a k -plex clutter matrix in polynomial time. It is also an interesting open problem to determine if k -plexes can characterize integral systems when $k > 2$.

This section offered a brief survey of results related to k -clique, k -clubs, and k -plexes. These results show that the theoretical aspects of clique relaxations have become an active area of research.

CONCLUSION

The clique concept is useful in many applications, but the definition of clique can be overly restrictive. The clique approach can fail to detect much of the structure present in a graph. This article discussed various ways of relaxing the clique concept, and it focused on k -plexes, k -clubs, and k -cliques.

The section titled “Combinatorial Algorithms” described a class of combinatorial algorithms by adapting a general clique algorithm to find k -plexes, k -clubs, and k -cliques. Such algorithms can benefit from the discovery of new bounding and pruning techniques. This line of work generally involves the development of heuristics, data reduction techniques, and preprocessing methods. These topics are an interesting area for future work.

The section titled “Theoretical Results” reviewed some recent complexity results, presented three integer programming formulations, and discussed polyhedral results. From a complexity standpoint, future work includes the identification of instances that admit polynomial time solutions. There also remains a great deal of work to be done on the study of k -plex, k -club, and k -clique polytopes, including the identification of strong inequalities and the recognition of polyhedra with simple structure.

CLOSED-LOOP SUPPLY CHAINS: ENVIRONMENTAL IMPACT

JACQUELINE M. BLOEMHOF
Wageningen University, BH
Wageningen, The Netherlands

CHARLES J. CORBETT
UCLA Anderson School of
Management, Los Angeles,
California

The context referred to under the heading “closed-loop supply chains” has, broadly speaking, two main origins. One deals with commercial returns, that is, products returned by customers for commercial reasons relatively soon after initial purchase; for instance, because the customer did not like the product, or because the product was defective. The other deals with end-of-life or end-of-use returns, where customers return products because they have reached the end of their technical life (for instance, when they become defective), or when they have reached the end of their economic life (for instance, when the customer decides to upgrade to a new model, or when a lease contract expires).

In this article, we focus on environmental impacts in three types of supply chains: (i) the traditional forward supply chains (in which disposal and return of materials are ignored), (ii) the extended forward supply chains (which consider disposal but no form of reprocessing), and (iii) environmental impacts in full closed-loop supply chains (which include forward chains and reprocessing of materials). Environmental impacts are also relevant in a forward supply chain, as the materials extracted from nature return to nature in the form of emissions or landfill and hence, form a closed loop in the natural cycle. Although other fields extensively discuss environmental impacts of systems, they rarely focus explicitly on how modifications in supply chain structures

or processes can improve environmental performance of the system.

The term *closed-loop supply chain* is used loosely in practice, referring either to “closed-loop” in the strict sense of the word, where previously used materials return to the original supply chain to be reused (in some form) in the same supply chain as before, or to “open-loop” systems, in which materials are taken back from customers but not necessarily reprocessed in the same supply chain as before. Reusable cameras that are taken back, reprocessed, and reintroduced as cameras into the same supply chain as before, are an example of a closed-loop supply chain; rubber tires, which are taken back after use and then reprocessed into road-surfacing material, are an example of an open-loop supply chain. We use the broad interpretation of “closed-loop” here.

The primary objective of closed-loop supply chain management is usually firm profitability [1]. That is unambiguous in the case of commercial returns, which were a business issue well before environmentally driven returns [2]. The environmental imperative is a major driver of the rapid growth in interest in closed-loop supply chains, hinging on the assumption that taking back and reprocessing materials is environmentally beneficial. Despite this environmental context, though, the vast majority of the closed-loop supply chain literature assumes that the objective is to increase the amount of materials taken back, or, alternatively, to minimize the cost of taking back materials (which presumably will in turn, increase the amount of materials taken back). Several studies indicate that that assumption does not always hold. For instance, Bloemhof-Ruwaard *et al.* [3] discuss how Scandinavian legislation requiring a certain proportion of paper to be recycled led to the environmentally undesirable outcome of wastepaper being shipped from the Netherlands and Germany to Scandinavia for recycling (refer also to **Recycling**). Similarly, Mayers *et al.* [4] shows that the exclusive focus on increasing take-back

embodied in the European Union's waste electrical and electronic equipment (WEEE) directive can be undesirable from a cumulative energy demand (CED) perspective.

The aim of this article is to introduce and exemplify the importance of environmental impact in closed-loop supply chain management. Many surveys exist of closed-loop supply chains (or green supply chains, or reverse logistics) [5–9]; for example, a special issue planned to appear in the journal *Production and Operations Management* in 2010, and others. However, the papers mentioned in these surveys do not explicitly deal with environmental impacts in a supply chain context, but instead use for example units returned as a measure for environmental impact. Here, we only focus on the explicitly measured environmental impacts in a supply chain context, in basic units such as megawatt hours, tons of CO₂, or others. We build our discussion on a limited set of articles that explicitly measure environmental impacts. It has been argued (see for instance Ref. 10 and the references therein) that including a broader set of metrics can help firms to find opportunities to improve financial performance of their supply chains that they may otherwise have missed. The close link between greenhouse gas emissions and fuel consumption provides many of the most immediate examples of firms achieving significant cost savings as a result of environmental objectives, but many less direct examples of this same mechanism also exist.

We start with a brief discussion of environmental impact measurement in general and provide resources for measuring environmental impacts. The structure of the rest of this article loosely follows the chronological development of environmental impact measurement in the supply chain context: first, we look at studies of environmental impacts in traditional forward supply chains (in which disposal and return of materials are ignored), then we turn to extended forward supply chains (which consider disposal but no form of reprocessing), after which we discuss environmental impacts in full closed-loop supply chains (which include forward chains and reprocessing of materials). The papers we discuss are intended primarily as

illustrations of how environmental impacts can be measured in closed-loop supply chains, rather than aiming to be a tutorial on how to perform such measurements.

MEASURING ENVIRONMENTAL IMPACTS

Many measures of environmental impacts exist, and no single measure unambiguously captures all impacts. Many studies based on life cycle assessment (LCA) methods consider the following seven main categories of environmental impacts: global warming potential (GWP), resource depletion, acidification, eutrophication, tropospheric ozone formation, ozone depletion, and human toxicity, though many of these in turn can be divided into subcategories. The Millennium Ecosystems Assessment (www.millenniumassessment.org, last accessed December 31, 2008) examines the state of 24 “ecosystem services” provided by the environment, including “provisioning services” (several types of food, fibers, genetic resources, biochemicals, natural medicines and pharmaceuticals, and fresh water), “regulating services” (including air quality regulation, global climate, local and regional climate, water regulation, erosion regulation, water purification and waste treatment, disease regulation, pest regulation, pollination, and natural hazard regulation), and “cultural services” (including spiritual and religious values, aesthetic values, and recreation and ecotourism).

In determining the environmental impacts of a closed-loop supply chain, we often want to know not only the direct impacts associated with a product, but also indirect ones, throughout its entire life cycle. This calls for an LCA, the process of defining a functional unit (unit of analysis) and scoping the system (setting the boundaries of impacts to be included), performing a life cycle inventory (LCI) of impacts associated with one functional unit within those boundaries, and then characterizing and interpreting those environmental impacts. For instance, to determine the environmental impacts of the printer supply chain, we would need to know the impacts of the

various mining and processing operations that yield the materials that go into the printer, but also (among many others) those that go into the packaging materials used at various stages in the forward and reverse part of the supply chain. A key decision in any LCA study is determining the scope of the study. For instance, a truly complete LCA would even require knowing the life cycle impacts associated with the production of the trucks used to transport the printers. In most practical cases, many of those indirect impacts can safely be ignored. Setting the boundaries of an LCA study appropriately therefore requires some knowledge of relative magnitudes of the impacts concerned. For that reason, some basic environmental numeracy is essential for scholars who study environmentally motivated problems.

Increasingly, researchers seek to simplify their analyses by aggregating impacts in the disparate categories mentioned above into a single metric, to facilitate further analysis and decision making. One such metric is cumulative fossil energy demand (or fossil CED), which aggregates primary energy used in all stages of a closed-loop supply chain. Given that use of fossil fuel is a major cause of global warming, and of depletion of fossil fuel supplies, CED is one metric that captures several of the key environmental impact categories. Huijbregts *et al.* [11] found that fossil CED also correlates well with most other impact categories, and hence can be a useful primary screening indicator, although they do caution that the high uncertainty in product-specific impact scores makes it difficult to use CED as a standalone impact measure.

A more complete summary representation of LCA results can be given in the form of a materials, energy, toxicity (MET) matrix, which shows the most important impacts in each of those three categories (the columns) associated with production, use, and disposal (the rows). Alternatively, it is common to select a few key environmental performance indicators (EPIs) that are particularly relevant for the given context and focus on those. A range of other tools, such as ecological

footprint (EF), environmental impact assessment (EIA), material flow accounting (MFA), material intensity per unit service (MIPS), and others, are discussed in Ref. 12.

RESOURCES FOR MEASURING ENVIRONMENTAL IMPACTS

Here we introduce some of the LCA approaches used in this field and provide pointers to resources for researchers who aim to include environmental impact measurements in their work.

Two common methods for conducting LCA studies are process-based LCA and economic input–output LCA. Process-based LCA involves specifying the stages of the system under consideration in detail, including all in- and out-flows of material and energy, and then determining (often using existing databases) the corresponding environmental impacts of each element of the process. Several software packages for process-based LCA are widely used in practice, including SimaPro (<http://www.pre.nl/simapro>, last accessed December 31, 2008), GaBi (<http://www.gabi-software.com>, last accessed December 31, 2008), and Umberto (<http://www.umberto.de/en/>, last accessed December 31, 2008). Although one can perform highly detailed LCA studies with these systems, they are relatively straightforward to use and are quite suitable for new users too.

Economic input–output life cycle assessment (EIO-LCA) involves specifying the economic system one is interested in, and modeling all economic flows into and out of that system, and then converting those flows into environmental impacts. A commonly used resource for EIO-LCA is the www.eiolca.net website maintained by the Green Design Initiative at Carnegie-Mellon University (www.eiolca.net). This relies on input–output analysis, and hence includes all direct and indirect environmental impacts associated with a certain volume of final product. One can choose, for instance, “tire manufacturing” from a drop-down menu of product types, and instantly learn that the total GWP associated with final sale of \$1 million worth

of rubber tires is 1090 metric tons of CO₂ (as of December 31, 2008), which can be further broken down into CO₂, N₂O, and other greenhouse gases; similarly for conventional air pollutants, energy, and toxic releases. Note that this includes emissions not just caused by tire manufacturers themselves, but also by their first, second, and higher tier suppliers.

Process-based LCA and EIOLCA both have advantages and disadvantages that are discussed in detail in the references below. Many good resources exist to learn more about environmental impact measurement and LCA:

- SETAC (The Society of Environmental Toxicology and Chemistry, see <http://www.setac.org>, last accessed January 6, 2009) provides a forum where scientists, managers, and other professionals exchange information and ideas for the development and use of multidisciplinary scientific principles and practices leading to sustainable environmental quality.
- The Institute of Environmental Sciences (CML) at the University of Leiden in the Netherlands is often considered one of the origins of LCA; their website (<http://www.leidenuniv.nl/cml/ssp/index.html>, last accessed December 30, 2008) provides some useful perspectives.
- For an extensive list of resources on LCA including a discussion of existing software, see <http://www.epa.gov/nrmrl/lcaccess/index.html> (last accessed December 30, 2008). Guidelines for conducting LCA studies include the ISO 14040:2006 and 14044:2006 standards.
- A site that focuses on LCA in a supply chain context is www.supplychainlca.com. Online courses on LCA are available from the following web sites:
- Royal Melbourne Institute of Technology (using SimaPro; see <http://simapro.rmit.edu.au>, last accessed December 30, 2008);
- Harvard School of Public Health (see www.sciencenetwork.com/lca, last accessed December 30, 2008);
- Professor Dave Allen at the University of Texas, Austin (see <http://www.utexas.edu/research/ceer/greenproduct> and <http://www.utexas.edu/research/ceer/greenmaterial>, last accessed December 30, 2008).

In what follows, we discuss several studies that measure environmental impacts in supply chains, primarily to illustrate the range of ways in which environmental impacts can be measured and how such information is used in the closed-loop supply chain context. There is a vast literature on applications of LCA which, by definition, have a supply chain element; here, we select a few studies that illustrate the range of uses of LCA in supply chains.

ENVIRONMENTAL IMPACTS IN FORWARD SUPPLY CHAINS

We start with some examples of earlier LCA studies in supply chains that do not explicitly consider disposal or recycling.

Table 1 summarizes the main research in this category. All papers make use of LCA, using a multifaceted index to measure the environmental impact in an industry, focusing on fuel choice and product and process design in process industries and transportation.

LCA studies invariably lead to environmental impacts, in addition to economic considerations. Hence, combinations of LCA with OR (operations research) techniques that facilitate dealing with multiple objectives are natural. In one of the earliest studies combining OR and LCA, Bloemhof-Ruwaard *et al.* [13] use LCA, linear programming (see section titled “Linear Programming (LP)” in this encyclopedia) and multicriteria decision making (MCDM) to compare environmental impacts of various fat blends. MCDM facilitates combining the environmental impact measures into a single index, while LP then allows the authors to determine the relative cost increase and environmental impact decrease that can be obtained with several environmentally optimized fat blends. Azapagic and Clift [14]

Table 1. Environmental Impacts in Forward Supply Chains

References	Research Questions	Solution Method	Application
13	How to compare environmental impacts of blends	LP + LCA + MCDM	Process industry (food)
14	How to include environmental impacts in process optimization	LP + LCA + MODM	Process industry (mining and minerals)
15	How to apply OR/MS tools to efficiently incorporate environmental legislation into production processes	NFM + nonlinear integer model	Process industry (copper)
16	How to compare environmental impact across various efficiency scenarios	LCA	Process industry (aluminum)
17	What are environmentally preferred vehicle options	LCA	Transportation (vehicles)
18	How to improve eco-efficiency at the fleet level	Eco-efficiency measure	Transportation (fleet)

apply a combination of LCA and multiobjective optimization to the boron system. This includes mining (for borax and kernite) and various processing steps leading to several boron products, and considers the seven impact categories mentioned before. As there are many ways to operate this system, a linear programming model is formulated to take into account market demand constraints, availability of primary and raw materials, production capacity, and heat requirements.

A nonlinear integer model combined with a network flow model is used by Caldentey and Mondschein [15] to design an optimal supply chain for the smelting and sulfuric acid production stages in the copper industry. Optimizing the entire system and allowing the market price for sulfuric acid to emerge endogenously rather than be imposed exogenously, enables the copper industry to earn substantially higher profits. It also allows decision makers to estimate the cost of government policies, such as new standards for arsenic emissions.

Tan and Khoo [16] report on an LCA study of the primary aluminum supply chain, consisting of mining, refining, smelting, casting, and power generation. The authors calculate GWP, acidification, human toxicity for air, resource consumption, and bulk wastes. They examine a base case, and scenarios with

progressively higher efficiency, starting with the case in which the casting plant reduces scrap metal by 20%, then one in which in addition the smelter implements more sustainable practices, and a final case in which the refinery also reduces bulk waste and the power plant uses clean coal technology.

As transportation is a major source of environmental impacts, many studies examine a range of transportation systems. Van Mierlo *et al.* [17] compare life cycle impacts of vehicles using two different methodologies: EcoScore (which attaches weights to impacts with respect to global warming, human health: respiration and cancer, ecosystems: acidification, buildings, and noise), and Cleaner Drive (which focuses on global warming and air quality). Although the two methodologies exhibit some differences, the insights they yield are largely consistent and both point toward battery-electric, hybrid and compressed natural gas (CNG) vehicles as the environmentally preferred options, with liquid petroleum gas (LPG) scoring fairly well, and petrol and diesel vehicles displaying wide variety in ratings. D'Agosto and Ribeiro [18] analyze improvement opportunities at the fleet level rather than for individual vehicles. They use the eco-efficiency measure (product or service value divided by environmental influence) as their basis for analysis, and focus on

CO₂ emissions from diesel oil, gasoline, ethanol, and CNG. Applying their approach to the fleet operations of Rio de Janeiro International Airport, they define landing and take-off cycles as the driver of service value, and then compare various scenarios, including converting all vehicles to CNG, implementing an eco-efficiency management plan, and replacing gasoline and CNG vehicles with hydrated ethanol.

It is not surprising to see much of the LCA-based work on forward supply chains focusing on the process industries and transportation sector. Both are a major source of emissions, so it is already worthwhile studying environmental impacts within this more limited scope, excluding extended and reverse supply chains. In the remainder, we see a continued focus on process industries and transportation, but also more consideration of industries where excluding extended and even reverse supply chains is less justifiable.

ENVIRONMENTAL IMPACTS IN EXTENDED FORWARD SUPPLY CHAINS

Progressively, authors have extended the boundaries of the supply chain to include end-of-life disposal. The first studies examine energy systems, where a good understanding

of the full energy implications of various materials and processing choices is of course essential. The remaining studies concern food supply chains, the electronics supply chain, and the vehicle life cycle.

Table 2 shows the three main application areas in which environmental impacts have been studied in extended supply chains: biomass, process industry, and transportation. The main issue in biomass research is to find economically and environmentally sound supply chain designs for renewable energy carriers. The main issue in the other areas of application is to assess the relative environmental impacts of all stages in the supply chain.

In view of the strong interest in biofuels as a source of renewable energy, especially when the biomass is derived from agricultural waste, a common question concerns the life cycle impacts of using biofuels when long-distance transportation of the biomass is required. Focusing on the functional unit of 1 MW of electricity delivered to the grid in an importing country, Forsberg [19] compares life cycle impacts in terms of energy expenditure (from electricity and fuel) and air emissions of various forms of biomass energy systems. Specifically, Forsberg [19] compares exporting forest residues after

Table 2. Environmental Impacts in Extended Forward Supply Chains

25	What is the trade-off between extending lifetime or frequent replacement?	LCA	Vehicle and fuel supply chain

making into bales or pellets in the form of tree sections, or generating and exporting the electricity derived from the biomass, and domestic use of the energy produced, and finds that, provided appropriate technology is used, biomass can be used to transport energy over long distances.

A more comprehensive analysis, including economic considerations, is reported in Ref. 20. They compare various supply chains for biomass, including transportation options for raw biomass (logs, bales, chips), for refined biomass (pellets, pyrolysis oil), and liquid biofuels (methanol) with the original biomass coming from Scandinavia, eastern Europe, or Latin America and being transported to western Europe. They also find that biomass can be transported over long distances in ways that are economically and environmentally sound, and provide recommendations for how to design the supply chain, specifically in which form the biomass should be transported and hence, which processing stages should take place close to where the biomass originates and which should be located close to where the energy is consumed. Sokhansanja *et al.* [21] develop an integrated simulation model to determine the cost, energy, and global warming implications of various supply chain designs defining how biomass is collected, stored, and transported to a processing facility.

The energy used in the food supply chain is often underestimated, as the following studies on milk and poultry illustrate. Soneson and Berlin [22] examine various scenarios for the extended supply chain for milk in Sweden, in the light of several metrics. Transport from retailers to households is easily the largest contributor to global warming, transport to the dairies is the largest contributor to NO_x , waste management has the largest impact in terms of eutrophication, and packaging production usually has the largest impact in terms of acidification. The results for formation of petrochemical oxidants vary more heavily across the scenarios. Pelletier [23] examines the multiple supply chains involved in poultry production, including the degree to which poultry litter displaces fertilizer production, and finds

that 80–98% of environmental impacts are associated with feed production rather than on-farm emissions, which is consistent with other studies cited therein on pork, beef, salmon, and milk.

One of the biggest drivers of interest in closed-loop supply chains is the WEEE Directive adopted by the European Union in 2003, which holds producers responsible for organizing and financing take-back, treatment, and recycling of WEEE. Mayers *et al.* [4] examine, for the case of recycling of HP printers in the United Kingdom, the impacts along seven dimensions of four different scenarios: 100% landfilling, partial or full recycling with no energy recovery from burning the plastics, and 99% recycling with energy recovery. The results are quite mixed: no scenario dominates, and higher recycling or energy recovery rates lead to worse environmental outcomes on some dimensions. Quariguasi Frota Neto *et al.* [24] also use the WEEE directive to illustrate a methodology for assessing eco-efficiency. They choose CED as their multifaceted environmental index in contrast to the single-faceted measure of waste diverted from landfill due to the WEEE directive, and use an optimization model to obtain iso-cost curves depicting the trade-off between CED (in MJ per year) and landfilled waste (in tons per year).

Using the eco-indicator 99 method, balancing the burdens associated with the vehicle and fuel supply chains, Spielmann and Althaus [25] finds that Swiss drivers should extend the life of their cars rather than replace them more frequently in order to benefit from increased fuel efficiency, though some of the results are sensitive to their specific assumptions.

Biomass is heavily represented in this category of extended forward supply chains, relative to the earlier category of forward supply chains, as the whole point of biomass supply chains is precisely in the final stage, where material is converted to energy. While the earlier section focused primarily on process choice and fuel choice, we see an increasing focus on product design and lifetime

extension in this category. The final category will consider more comprehensive supply chain issues, including both process and product design.

ENVIRONMENTAL IMPACTS IN CLOSED-LOOP SUPPLY CHAINS

The final set of studies we discuss consider environmental impacts in entire closed-loop supply chains, including various forms of reprocessing, whether in the form of reuse, recycling, or other. The first studies examine bulk materials (lumber, paper and pulp, packaging, and steel); the subsequent studies examine more complex products (photocopiers, refrigerators, and various electrical and electronic products).

Table 3 shows that the research questions in this category all deal with a combination of improvements that can be made in the forward chain (lifetime extension, design, incineration) and in the reverse chain (recycling, remanufacturing, reuse). As the supply chains under investigation are complex and

both environmental and economic objectives have to be considered, the solution methods are a combination of LCA and Operations Research/Management Science optimization models.

Sathre and Gustavsson [26] examine the global warming effects of various uses for recovered wood lumber (reuse as lumber, reprocessing as particleboard, pulping, and energy recovery). They find that the degree to which forest land is constrained, and hence the degree to which it can be put to alternative uses, is a major factor in determining which cascade is preferred.

Bloemhof-Ruwaard *et al.* [3] model the European paper and pulp supply chain using a linear network flow model, distinguishing various pulping and bleaching techniques and allowing relocation of paper production. They compare a number of regulatory scenarios in terms of the seven main environmental categories and a single environmental index. Quariguasi Frota Neto *et al.* [27] build on this work and also finds that mandatory recycling targets can have limited or even counterproductive

Table 3. Environmental Impacts in Closed-Loop Supply Chains

References	Research Questions	Solution Method	Application
26	What are the global warming effects of uses for recovered product?	Carbon balance	Natural resources (wood lumber)
27	What is the environmental impact of an integrated closed-loop supply chain?	Linear programming	Process industry (paper and pulp)
28	What is the trade-off between single-use and reusable packaging?	EIOLCA	Packaging

environmental effects. Matthews [28] illustrates use of the EIOLCA method in a case study at Quantum Corporation comparing a conventional single-use packaging with a packaging designed for reuse, and finds that, even taking the increased transportation into account, reusable packaging can lead to lower costs and substantial improvements in energy usage, GWP, and various air pollution measures.

Quite some work has been done on comparing options for reuse. Geyer and Jackson [29] compare various options for reuse of steel (recovering steel sections through deconstruction and reusing them, or recovering steel via demolition and recycling, or landfill) in terms of life cycle cost and energy use. They find that constraints on reuse have limited impact on environmental performance but significant impact on economic performance. Björklund and Finnveden [30] survey a collection of LCA case studies that compare recycling, incineration, and landfill, finding that for most of the products they consider (glass, metals, plastics, paper, cardboard) the ranking between the three options is often quite clear. Daniel *et al.* [31] carried out an LCA study on alternative end-of-life scenarios for used starter batteries. They focus on the question of which methodology to choose in the impact assessment (IA) step of the LCA. They concluded that the effectiveness of the LCA is improved if as many IA methods as possible are used in a study, so decision makers can choose the method which best fits the specific features of the system examined.

Fleischmann *et al.* [32] compare networks in which the forward and reverse flows are optimized sequentially with those in which both flows are optimized simultaneously. In the case of copiers, where production facilities tend to be relatively close to the markets, a reverse flow can be added to an existing forward network with few complications. In contrast, in the paper industry, production locations are typically located close to natural resources (raw materials) and far from customer markets, so adding a reverse flow prompts a drastically different network design.

Krikke *et al.* [33] modify a case study of a Japanese company's supply chain for refrigerators in Europe to examine trade-offs between cost, waste, and energy use, finding that (for their scenarios) the supply chain network has the most impact on cost, while product design has the most impact on energy use and waste. Moreover, they find that recovery targets based on proposed legislation have an ambivalent impact; they reduce waste but increase energy use and costs. Quariguasi Frota Neto *et al.* [34] explore which phase in a supply chain produces the largest life cycle environmental impacts (measured by CED), in order to determine whether one should focus on improving product design (to increase energy efficiency), longer product life cycles, or more remanufacturing (See **Recycling**). For the two relatively high-tech electronic products they consider (PCs and mobile phones), the CED is driven primarily by the manufacturing stage, so that product life extension and reuse and remanufacturing of components provide the largest environmental improvements. Conversely, for the three relatively low-tech electrical products they consider (washing machines, refrigerators, and televisions), the main impacts are in the usage phase, so that focusing on energy-efficient designs has more promise.

Summarizing, we see that despite the complexity of the supply chains considered, a combination of existing LCA and OR/MS methods can yield valuable insights into optimal design of products and of forward and reverse supply chains.

CONCLUSIONS

From the studies reviewed here, several observations emerge. A wide range of approaches and methodologies exist for combining actual environmental impact measurement in models of closed-loop supply chains, and they yield valuable insights into the key trade-offs between various environmental and economic metrics. On the other hand, many of the findings about which stage in a supply chain causes higher impacts on any given metric are often specific to that metric and to that context, making

it challenging to draw general conclusions about which metrics or supply chain stages to focus on. We believe the rich and rapidly growing set of tools available to scholars today to incorporate explicit environmental impact measures into their models of closed-loop supply chains makes this a promising and crucial area for future growth of the field.

This article aims to show that including explicit environmental impact measurements in models of closed-loop supply chains is not only feasible, it is in fact considerably easier to do than is often assumed. With the examples provided by the papers discussed here, and the resources referred to above, we hope that scholars of closed-loop supply chains will attempt to include more complete environmental impact measures in their models rather than focusing exclusively on the number of units reprocessed. Even if a full LCA study is usually far beyond the scope of most closed-loop supply chain models, the materials summarized here provide examples of how, for any given context, one can obtain preliminary assessments of which stages in a supply chain dominate in terms of specific impact categories.

For products with high environmental impacts during production, extension of product lifetime will reduce environmental impact per unit of time. Therefore, strategies such as repair, refurbishing, and remanufacturing are environmentally beneficial. However, this is very product-specific, as sometimes the higher energy efficiency of new equipment can make it undesirable to extend the life of old equipment. In any event, at the end of its useful life, every product can be recycled in some form. For some products, however, the proportion of virgin materials and energy that can be reclaimed by recycling is very small compared to the effort that is needed (in transportation, shredding, reclaiming, etc.), so that total environmental impact improvement can even be negative. Therefore, the key prerequisite for environmental improvements in closed-loop supply chains is to understand the life cycle economic and environmental impacts of the product in question, at a richer level than is often done so far.

CLUSTERING

CEM IYIGUN
Department of Industrial
Engineering, Middle East
Technical University,
Ankara, Turkey

Clustering is the classification of objects into different groups, or more precisely, the partitioning of a data set into subsets (clusters), so that the data in each subset (ideally) share some common trait—often proximity according to some defined distance measure. *Data clustering* is a common technique for statistical data analysis, which is used in many fields, including machine learning, data mining, pattern recognition, image analysis, and bioinformatics [1].

The ideas and methods of clustering are used in many areas, including *statistics* [2], *machine learning* [3], *data mining* [4], *operations research* [5,6], *medical diagnostics*, *facility location*, and across multiple application areas including genetics, taxonomy, medicine, marketing, finance and e-commerce (see Refs 7–10 for applications of clustering). It is therefore useful to begin by stating our notation and terminology. We then survey some of the clustering algorithms and methods.

NOTATION AND TERMINOLOGY

Data

The objects of clustering are *data points* (also *observations*, and in facility location, *customers*.) Each data point is an ordered list of *attributes* (or *features*), such as height, weight, blood pressure, and so on. Assuming p attributes, a data point $\mathbf{x}$ is thus a p -dimensional vector, $\mathbf{x} = (x_1, x_2, \dots, x_p)$, with the attributes x_i for components.

The vector analogy cannot be carried too far, since, in general, vector operations (such as vector addition, scalar multiplication) do

not apply to data points. Also, the attributes are not necessarily of the same algebraic type; some may be categorical, and others are reals. However, we can always imbed the data points in a p -dimensional real vector space $\mathbb{R}^p$, and for convenience we denote by $\mathbf{x} \in \mathbb{R}^p$ the fact that the data point $\mathbf{x}$ has p attributes.

We assume N data points $\mathbf{x}_i$, collected in a set

$$\mathcal{D} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N\} \subset \mathbb{R}^p, \quad (1)$$

called the *data set*. We sometimes represent $\mathcal{D}$ by an $N \times p$ matrix

$$D = (x_{ij}), \text{ where } x_{ij} \text{ is the } j\text{th component} \\ \text{of the data point } \mathbf{x}_i. \quad (2)$$

The Problem

Given the data set $\mathcal{D}$, and integer K , $1 \leq K \leq N$, the *clustering problem* is to partition the data set $\mathcal{D}$ into K disjoint clusters

$$\mathcal{D} = \mathcal{C}_1 \cup \mathcal{C}_2 \cup \dots \cup \mathcal{C}_K, \quad \text{with} \\ \mathcal{C}_j \cap \mathcal{C}_k = \emptyset \text{ if } j \neq k, \quad (3)$$

each cluster consisting of points that are *similar* (in some sense) and points of different clusters being dissimilar. We take here, *similar*, to mean *close* in the sense of *distances* $d(\mathbf{x}, \mathbf{y})$ between points $\mathbf{x}, \mathbf{y} \in \mathbb{R}^p$. The *number of clusters* denoted by K is given; however, there are problems where the “right” number of clusters (to fit best the data) is to be determined. The cases $K = 1$ (the whole $\mathcal{D}$ is one cluster) and $K = N$ (every point is a separate cluster) are included for completeness.

Cluster Membership

A clustering is *hard* (or *crisp*, *rigid*, *deterministic*) if each data point $\mathbf{x}$ is assigned to one and only one cluster $\mathcal{C}$, so that the statement $\mathbf{x} \in \mathcal{C}$ is unambiguous.

A point $\mathbf{x}$ is *labeled* if its cluster $\mathcal{C}$ is known, in which case $\mathcal{C}$ is the *label* of $\mathbf{x}$.

In *soft* (or *fuzzy*, *probabilistic*) clustering the rigid assignment $\mathbf{x} \in C$ is replaced by a *cluster membership function* $u(\mathbf{x}, C)$ representing the *belief* that x belongs to C . The numbers $u(\mathbf{x}, C_k)$ are often taken as probabilities that $\mathbf{x}$ belongs to C_k , so that

$$\sum_{k=1}^K u(\mathbf{x}, C_k) = 1, \text{ and } u(\mathbf{x}, C_k) \geq 0 \\ \text{for all } k = 1, \dots, K. \quad (4)$$

Classification

In *classification* or *supervised learning*, the number K of clusters is given, and a certain subset $\mathcal{T}$ of the data set $\mathcal{D}$ is given as labeled, that is, for each point $\mathbf{x} \in \mathcal{T}$ it is known to which cluster it belongs. The subset $\mathcal{T}$ is called the *training set*.

The information obtained from the training set, is then used to find a rule for classifying the remaining data $\mathcal{D} \setminus \mathcal{T}$ (called the *testing set*), and any future data of the same type, to the K clusters. The *classification rule* r is a function from $\mathcal{D}$ (and by extension $\mathbb{R}^p$) to the integers $\{1, 2, \dots, K\}$, so that

$$r(\mathbf{x}) = k \iff \mathbf{x} \in C_k.$$

In analogy, clustering is called *unsupervised learning* to emphasize the absence of prior information.

Similarity and Dissimilarity

Some cluster analysis techniques begin with transforming the matrix $\mathcal{D}$ into an $N \times N$ matrix of data points of *similarities* or *dissimilarities* (a general term is *proximity*). The *similarity* between two data objects is a numerical measure of the degree to which the objects are alike. Naturally, the more alike the objects are, the higher the similarities are. Similarities are usually nonnegative and often take values between 0 and 1. On the other hand, the *dissimilarity* between two objects is a numerical value measuring the degree to which the objects are different. Dissimilarities are lower for more similar data objects. Although the *distance* is used as synonym for dissimilarities, distance is

a special class of dissimilarities. Dissimilarity measures mostly range from 0 to ∞ , but they also take values in the range of $[0, 1]$. In the following sections, we provide some general examples of similarity and dissimilarity measures.

Similarity Measures

Let similarity between two data points $\mathbf{x}, \mathbf{y} \in \mathbb{R}^p$ be defined by $s(\mathbf{x}, \mathbf{y})$. If the data points contain only binary values the similarity measures $s(\mathbf{x}, \mathbf{y})$, are called *similarity coefficients*. The comparison of two binary data points leads to different similarity measures. All the measures are defined in terms of the counts of matches and mismatches in p variables of two data binary points. One commonly used similarity coefficient, *matching coefficient* is defined as

$$s(\mathbf{x}, \mathbf{y}) = \frac{f_{00} + f_{11}}{\text{number of attributes}}, \quad (5)$$

where f_{00} and f_{11} are the number of attributes that both data points take the value 0 and 1, respectively.

Suppose that $\mathbf{x}$ and $\mathbf{y}$ are two data objects that have different number of attributes. In such cases, the *Jaccard coefficient* is frequently used to handle asymmetric binary attributes. The *Jaccard coefficient* $\mathcal{J}$, is given by the following equation:

$$\mathcal{J}(\mathbf{x}, \mathbf{y}) = \frac{f_{11}}{\text{number of attributes excluding } f_{00}}. \quad (6)$$

The *cosine similarity*, which depends on the *standard inner product* of two vectors is another similarity measure that is commonly used.

Assuming a norm $\|\cdot\|$ on the space $\mathbb{R}^p$, the *standard inner product* of $\mathbf{x} = (x_1, \dots, x_p)$ and $\mathbf{y} = (y_1, \dots, y_p)$ is defined by

$$\langle \mathbf{x}, \mathbf{y} \rangle = \sum_{i=1}^p x_i y_i. \quad (7)$$

Then the *cosine similarity* is defined as

$$\cos(\mathbf{x}, \mathbf{y}) = \frac{\langle \mathbf{x}, \mathbf{y} \rangle}{\|\mathbf{x}\| \cdot \|\mathbf{y}\|}. \quad (8)$$

Actually, cosine similarity is a measure of the angle between $\mathbf{x}$ and $\mathbf{y}$. Thus, if the cosine similarity is 1, the angle between $\mathbf{x}$ and $\mathbf{y}$ is 0° , and $\mathbf{x}$ and $\mathbf{y}$ are the same except for the length. When the cosine similarity is 0, the angle between $\mathbf{x}$ and $\mathbf{y}$ is 90° , and these two data points do not have any similarities.

Dissimilarity and Distance Measures

When all the attributes are continuous, proximities between data points are typically measured by dissimilarity measures or distance measures. *Distance measures* are the important class of dissimilarity measures with certain properties. Generally, a dissimilarity measure $\delta(\mathbf{x}, \mathbf{y})$, fulfilling the metric axioms is termed as a *distance measure*.

Assuming a norm $\|\cdot\|$ on the space $\mathbb{R}^p$, a distance between two points $\mathbf{x}, \mathbf{y} \in \mathbb{R}^p$ is defined by

$$d(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|, \quad (9)$$

for example, the Euclidean norm gives the distance between $\mathbf{x} = (x_1, \dots, x_p)$ and $\mathbf{y} = (y_1, \dots, y_p)$ as

$$d(\mathbf{x}, \mathbf{y}) := \left(\sum_{j=1}^p (x_j - y_j)^2 \right)^{1/2}, \quad \text{the Euclidean distance}, \quad (10)$$

and the ℓ_1 -norm gives

$$d(\mathbf{x}, \mathbf{y}) := \sum_{j=1}^p |x_j - y_j|, \quad \text{the } \ell_1\text{-distance}, \quad (11)$$

also called the *Manhattan* or *taxicab distance*.

If $\mathbf{Q}$ is a positive-definite $p \times p$ matrix, then $\sqrt{\langle \mathbf{x}, \mathbf{Q} \mathbf{x} \rangle}$ is a norm on $\mathbb{R}^p$, and the corresponding distance is

$$d(\mathbf{x}, \mathbf{y}) := \sqrt{\langle \mathbf{x} - \mathbf{y}, \mathbf{Q}(\mathbf{x} - \mathbf{y}) \rangle}, \quad \text{an elliptic distance}, \quad (12)$$

depending on the choice of $\mathbf{Q}$. For $\mathbf{Q} = \mathbf{I}$, the identity matrix, Equation (12) gives the

Euclidean distance (10). Another common choice is $\mathbf{Q} = \Sigma^{-1}$, where Σ is the covariance matrix of the data in question, in which case Equation (12) gives

$$d(\mathbf{x}, \mathbf{y}) := \langle \mathbf{x} - \mathbf{y}, \Sigma^{-1}(\mathbf{x} - \mathbf{y}) \rangle, \quad \text{the Mahalanobis distance}, \quad (13)$$

that is used commonly in multivariate statistics.

Distances associated with norms satisfy the *triangle inequality*,

$$d(\mathbf{x}, \mathbf{y}) \leq d(\mathbf{x}, \mathbf{z}) + d(\mathbf{z}, \mathbf{y}), \quad \text{for all } \mathbf{x}, \mathbf{y}, \mathbf{z}. \quad (14)$$

However, distance functions violating Equation (14) are also used.

Similarity Data

Given a distance function $d(\cdot, \cdot)$ in $\mathbb{R}^p$, and the data set $\mathcal{D}$, the *dissimilarity* (or *proximity*) *matrix* of the data is the $N \times N$ matrix

$$\delta = (d_{ij}), \quad \text{where } d_{ij} = d(\mathbf{x}_i, \mathbf{x}_j), \quad i, j = 1, \dots, N. \quad (15)$$

It is sometimes convenient to work with the *similarity matrix*,

$$S = (g(d_{ij})), \quad \text{where } g(\cdot) \text{ is an increasing function}. \quad (16)$$

Representatives of Clusters

In many clustering methods a cluster is represented by a typical point, called its *center* (also *representative*, *prototype*, and in facility location, *facility*.) A common choice for the center is the *centroid* of the points in the cluster. The cluster centers can happen to be the data points in the clusters.

The center of the k th cluster C_k is denoted by $\mathbf{c}_k$, and the distance $d(\mathbf{x}, C_k)$ of a point $\mathbf{x}$ from that cluster is defined as its distance

4 CLUSTERING

from the center $\mathbf{c}_k$,

$$d(\mathbf{x}, \mathcal{C}_k) := d(\mathbf{x}, \mathbf{c}_k), \quad (17)$$

and denoted $d_k(\mathbf{x})$, if the center is understood.

Objective Function of Clustering

Sometimes the “goodness” of clustering can be expressed by an *objective function* of the given data $\mathcal{D}$ and the clusters $\{\mathcal{C}_1, \dots, \mathcal{C}_K\}$ (see the section titled “Dispersion Statistics” for more details). For example,

$$f(\mathcal{D}, \{\mathcal{C}_1, \dots, \mathcal{C}_K\}) = \sum_{k=1}^K \sum_{\mathbf{x}_i \in \mathcal{C}_k} d(\mathbf{x}_i, \mathbf{c}_k) \quad (18)$$

is the sum of distances of data points to the centers of their respective clusters, while

$$f(\mathcal{D}, \{\mathcal{C}_1, \dots, \mathcal{C}_K\}) = \sum_{k=1}^K \sum_{\mathbf{x}_i \in \mathcal{C}_k} d(\mathbf{x}_i, \mathbf{c}_k)^2 \quad (19)$$

is the sum of squares of these distances.

In such cases, clustering reduces to an *optimization problem*, that without loss of

Algorithm 1. *k*-means Clustering Algorithm.

Step 0 Initialization: Given data set $\mathcal{D}$, integer K , $2 \leq K < N$,

select K initial centers $\{\mathbf{c}_k\}$

Step 1 Compute the distances $d(\mathbf{x}_i, \mathbf{c}_k)$, $i = 1, \dots, N$, $k = 1, \dots, K$.

Step 2 Partition the data set $\mathcal{D} = \mathcal{C}_1 \cup \mathcal{C}_2 \cup \dots \cup \mathcal{C}_K$ by assigning each data point to the cluster whose center is the nearest

Step 3 Recompute the cluster centers.

Step 4 If the centers have not changed or the change is smaller than a threshold, **stop**.
else go to Step 1.

Notes

1. The initial “centers” in Step 0 are just points, and not yet associated with clusters. There are several ways to initialize the cluster centers. One way is to randomly select K points from the data set. The other way is to randomly generate K points evenly distributed in the space spanned by the data set $\mathcal{D}$.
2. In Step 3 the center of each cluster is computed using the points assigned to that cluster.

generality, is considered a *minimization problem*,

$$\min_{\mathcal{C}_1, \dots, \mathcal{C}_K} f(\mathcal{D}, \{\mathcal{C}_1, \dots, \mathcal{C}_K\}), \quad (20)$$

which is often hard (combinatorial, non-smooth), but approximate solutions of Equation (20) may be acceptable.

CENTER-BASED CLUSTERING METHODS

Center-based clustering algorithms construct the clusters using the distances of data points from the cluster centers.

The best-known and most commonly used center-based algorithm is the *k-means algorithm* [11,12], which (implicitly) minimizes the objective

$$\sum_{k=1}^K \sum_{\mathbf{x}_i \in \mathcal{C}_k} \|\mathbf{x}_i - \mathbf{c}_k\|^2, \quad (21)$$

where $\mathbf{c}_k$ is the centroid of the k^{th} cluster. Other names like hard *k*-means and ISO-DATA [13,14] have also been used in the literature.

3. The stopping rule in Step 4 implies that there are no further reassignments.
4. The center updates in the iterations are computed by

$$\mathbf{c}_k = \frac{\sum_{i=1}^N u_{ik} \mathbf{x}_i}{\sum_{i=1}^N u_{ik}}, \quad k = 1, \dots, K, \quad (22)$$

where $u_{ik} = 1$, if $\mathbf{x}_i \in \mathcal{C}_k$, and $u_{ik} = 0$ otherwise. Equation (22) gives the

centers as the geometrical centroids of the data points of the cluster.

5. Using Euclidean distances, iterating Steps 2 and 3 leads to the minimization of the objective (21).

Variants of the k -Means Algorithm

Several variants of k -means algorithm have been reported in the literature [15,16]. Some of them attempt to select a good initial partition so that the algorithm is more likely to find the global minimum value [17]. An important variant of the algorithm is to permit splitting and merging of the resulting clusters [13] in Step 2 of the algorithm.

Some variants of the algorithm use different criteria. Diday [18] used different representatives of the clusters (other than the cluster centers), and the Mahalanobis distance is used instead of the Euclidean distance in Mao and Jain [19], Cheung [20], and elsewhere.

The *k-modes algorithm* [21] is a recent center-based algorithm for categorical data. It utilizes a simple matching dissimilarity measure, which is the total number of mismatches of the categorical attributes of the objects between two categories [2]. Another variant, the *k-prototypes algorithm* [21], incorporates real and categorical data. It combines the k -means and k -modes processes in order to cluster data with numerical and categorical values. The dissimilarity measure in the k -prototypes algorithm is defined as a weighted sum of the dissimilarity measure on numerical attributes (just the squared Euclidean distance) and the simple matching dissimilarity measure on categorical attributes.

Fuzzy k -Means

The k -means algorithm can be adapted to soft clustering (see section titled “Cluster Membership”). A well-known center-based algorithm for soft clustering is the *fuzzy k -means algorithm* [22,23].

The objective function minimized in this algorithm is

$$f = \sum_{i=1}^N \sum_{k=1}^K u_{ik}^m d_{ik}^2 = \sum_{i=1}^N \sum_{k=1}^K u_{ik}^m \|\mathbf{x}_i - \mathbf{v}_k\|^2,$$

where u_{ik} are the membership functions of $\mathbf{x}_i \in C_k$, and typically satisfy Equation (4), and m is a real number, $m > 1$, known as *fuzzifier*.

The equation for finding the centers is similar to Equation (22) of the k -means algorithm, but u_{ik} takes values between 0 and 1.

$$\mathbf{c}_k = \frac{\sum_{i=1}^N u_{ik}^m \mathbf{x}_i}{\sum_{i=1}^N u_{ik}^m}, \quad k = 1, \dots, K. \quad (23)$$

When m tends to 1, the algorithm converges to the k -means method.

HIERARCHICAL CLUSTERING ALGORITHMS

Hierarchical clustering algorithms are an important class of clustering methods that do not group data into particular clusters represented by centers, but instead a series of partitions to the data set or clusters are merged and a hierarchy of clusters is created.

These algorithms transform a similarity data set into a tree-like structure which is called a *dendrogram* [24]. The root of the dendrogram consists of a single cluster containing all observations (data points), and the leaves correspond to individual observations. In the middle, child clusters partition the points assigned to their common parent according to a similarity measure. This is illustrated in Fig. 1. (Note that the dendrogram is not a binary tree.) Hierarchical clustering methods are generally categorized into two major methods as *agglomerative*, in which one starts at the leaves and successively merges clusters together; and *divisive* [2,10], in which one starts at the root and recursively splits the clusters.

Agglomerative clustering is a bottom-up way of constructing the dendrogram. It starts with N clusters, each has one point (singleton), and recursively merges two or more most similar clusters until all N data points are in a single cluster (which is the root of dendrogram). On the other hand, *divisive* clustering starts from the root, a top-down way of constructing the dendrogram. It starts at the root with one cluster containing all N

Figure 1. An example of the dendrogram that might be produced by a hierarchical algorithm from the data shown in (a). The dashed lines indicate different partitions at different levels of similarity.

data points and recursively splits the clusters until N clusters are formed or until a stopping criterion (frequently, the requested number k of clusters) is achieved. Agglomerative techniques are more commonly used than divisive techniques, because they are computationally less complex.

For agglomerative hierarchical techniques, the criterion is typically to merge the *closest* pair of clusters, where *close* is defined by a specified measure of cluster proximity. There are three definitions of the closeness (linkage metrics) between two clusters: *single-link*, *complete-link*, and *average-link*. The *single-link* similarity between two clusters is the similarity between the two most similar instances, one of which appears in each cluster. Single link is good at handling nonelliptical shapes, but is sensitive to noise and outliers. The *complete-link* similarity is the similarity between the two most dissimilar points, one from each cluster. Complete link is less sensitive to noise and outliers, but can break large clusters, and it favors globular shapes. The *average-link* similarity is a compromise between the two. In this version, proximity of two clusters is the average of pairwise proximity between points in the two clusters. *Average-link* is also less susceptible to noise and outliers as in *complete-link*. The advantages of agglomerative and divisive algorithms are the following: (i) they do not require to prespecify the number of clusters in advance, (ii) they compute a complete hierarchy of clusters, (iii)

good result visualizations are integrated into the methods, and (iv) a *flat* partition can be derived afterwards (using a cut through the dendrogram). However, both methods suffer from their inability to perform adjustments once the splitting or merging decision is made. If a misclassification is made at one point during the growth of the dendrogram, it is carried on until the end of the process. It is not possible to correct the misclassification during the clustering process. After the tree structure has been constructed, different clustering interpretations can be performed.

Although the number of clusters is not predefined in hierarchical clustering, when to stop the partition in a divisive algorithm or when to stop the merging in an agglomerative algorithm are important questions. At which level should the tree be cut or at which value of similarity (or dissimilarity) should the dendrogram be cut are practical questions. All such questions lead to deciding how many clusters are present. The usual practice being that a large disparity in the levels of dendrogram at which clusters merge indicates the presence of natural groupings. Different heuristics may be used to answer the question. Although it does not always work, choosing a value of dissimilarity such that there is a large *gap* in the dendrogram is commonly used as a heuristic [25]. Moreover, various validity indices for hierarchical clustering are also used for determining where to stop the dendrogram [26]. The index measure is evaluated in different stages of the

hierarchical clustering and the graphing the index values for different levels of dendrogram helps determining the number of clusters.

In hierarchical clustering, the regular data matrix representation (which is point-by-attribute data) is sometimes of secondary importance. Instead, hierarchical clustering frequently deals with the similarity (or dissimilarity) matrix between the data points. It is sometimes called *connectivity matrix*. Linkage metrics are constructed from elements of this matrix.

There are many different hierarchical clustering algorithms presented in the literature. Some of them are Balanced Iterative Reducing and Clustering using Hierarchies *BIRCH* [27], Clustering Using Representatives *CURE* [28], and *CHAMELEON* [29]. Robust Clustering Algorithm for Categorical Attributes (*ROCK*) [30] is another clustering algorithm using the Jaccard coefficient to measure similarity. More recently, a novel incremental hierarchical clustering algorithm, *GRIN*, for numerical data sets is presented in Chen *et al.* [31]. A survey and comparison of these algorithms are in Kotsiantis and Pintelas [32] and Berkhin [33].

OTHER CLUSTERING METHODS

In this section, we briefly describe other clustering methods developed in the data clustering area. For comprehensive explanations and further details, see the cited references.

Probabilistic Clustering

Probabilistic clustering refers to data sets whose points come from a known statistical distribution, whose parameters have to be estimated. Specifically, the data may come from a mixture of several distributions and the weights of the distributions in the mixture, and their parameters, have to be determined.

The best-known probabilistic method is the *expectation-maximization (EM) algorithm* [34] where log-likelihood of the data points drawn from a given mixture model. The underlying probability model and its parameters determine the membership function of the data points. The algorithm starts

with initial guesses for the mixture model parameters. These values are then used to calculate the cluster membership functions for the data points. In turn, these membership functions are used to re-estimate the parameters, and the process is repeated.

Another probabilistic clustering method is *AUTOCLASS* [35], which also uses the mixture model and extends the search to different models and different k distributions. The method relies on Bayesian methodology and is applicable both continuous and categorical data. The algorithm starts with a random initialization of the parameters, then iteratively updates them to find their maximum likelihood estimates. Furthermore, Pena *et al.* [36] assume that there is a hidden variable reflecting the cluster membership for every data point, besides the observed variables. Using the hidden variable, the clustering problem as a supervised learning from incomplete data [37] and a learning algorithm, called *RBMNs* (recursive Bayesian multinets), relying on Bayesian methodology can be used for clustering.

Probabilistic methods depend critically on their assumed priors. If the assumptions are correct, one gets good results. A drawback of these algorithms is that they are computationally expensive. Another problem found in this approach is called the *overfitting* [38].

Density-Based Clustering

Density-based methods consider that clusters are dense sets of data points separated by less dense regions; clusters may have arbitrary shape and data points can be arbitrarily distributed. The concepts of *density*, *connectivity*, and *boundary*, which are related to a point's neighborhood are required in clustering the data points. In density-based clustering, the neighborhood of a data point is defined with a given radius (*Eps*), which contains at least a minimum number of data points (*MinPts*). The algorithm is guided by the density of the points and it can find clusters having arbitrary shapes.

DBSCAN [39] is one of the most common density-based clustering algorithm. It is further improved in Kotsiantis and Pintelas [32], called the *GDBSCAN* algorithm, which generalizes the DBSCAN algorithm

for clustering data points with both numerical and categorical attributes. A parallel version of DBSCAN algorithm is developed in Xu *et al.* [40]. Moreover, the *DBCLASD* algorithm (Distribution-based Clustering of Large Spatial Data Sets), introduced by Xu *et al.* [41], eliminates the need for *MinPts* and *Eps* parameters.

One can consider within the category of density-based methods, the *grid-based solutions*, such as *DENCLUE* [42] or *CLIQUE* [43], mostly developed for spatial data mining. These methods quantize the space of the data points into a finite number of cells (attention is shifted from data points to space partitioning) and only retain for further processing the cells having a high density of points; isolated data points are thus ignored. Quantization steps and density thresholds are common parameters for these methods.

Graph-Theoretic Clustering

Another clustering method is the *graph-theoretic clustering* method, where the data points are represented as nodes in a graph and the dissimilarity between two points is the “length” of the edge between the corresponding nodes. In several methods, a cluster is a subgraph that remains connected after the removal of the longest edges of the graph [10]; for example, in Zahn [44] (the best-known graph-theoretic clustering algorithm) the minimal spanning tree of the original graph is built and then the longest edges are deleted. Some other graph-theoretic methods rely on the extraction of *cliques* and are then more related to center-based methods [45].

Model-Based Clustering

SOM(self-organizing map)net, introduced by Teuvo Kohonen, is a model-based method [46]. It is a type of artificial neural network, which is trained using unsupervised learning. The method can be thought as two layers of neural network using a neighborhood function to preserve the topological properties of the input space [47]. Each neuron of the network is the cluster center represented by the n -dimensional weight vector. SOM algorithm works in two modes: training and mapping. Training creates the map using the input

vectors that are also called *vector quantization*. SOM is trained iteratively. In each training step, one input vector is randomly chosen from the input data set, and the distance between the input vector and all the weight vectors of the SOM is calculated using a distance measure. The neuron whose weight vector is closest to the input is called best-matching unit. After finding the best-matching unit, the weight vectors of SOM are updated such that best-matching unit is moved closer to the input vector. The SOM method is robust and insensitive to outliers. It can easily detect the outliers and can handle the missing data.

Volume-Based Clustering

To overcome the difficulties like clustering with equal size or spherical shapes, we can use Mahalanobis distances (see the section titled “Dissimilarity and Distance Measures”) instead of Euclidean distance [48]. For example, if the covariance Σ is known, then the similarity within that cluster, with center $\mathbf{c}$ would be measured by $\|\mathbf{x} - \mathbf{c}\|_{\Sigma^{-1}}$. This measure is scale invariant and can deal with asymmetric, nonspherical clusters. A difficulty in using Mahalanobis distances is getting a good estimate of the covariance matrices in question.

A promising alternative scale-invariant metric of cluster quality are *minimum volume ellipsoids*, where data points are allocated into clusters so that the volumes of the covering ellipsoids for each cluster is minimized. The problem of finding the minimum volume ellipsoid can be formulated as a *semidefinite programming* problem and an efficient algorithm for solving the problem has been proposed by Sun and Freund [49].

Biclustering

Biclustering is a clustering method in which the rows and columns of a data matrix are grouped simultaneously. It is also named as *co-clustering* or *two-mode clustering* [50]. Given a data matrix with m rows and n columns, the biclustering algorithm generates subset of rows (columns), which show similar behavior across a subset of columns (and rows) in a given data set. Biclustering

has been used in *text mining* and *bioinformatics* (i.e., gene expression analysis [51]).

There are many biclustering algorithms developed for bioinformatics, in the literature. Some of them are block clustering, coupled two way clustering (CTWC) [52], δ -bicluster [51], δ -Cluster, Gibbs, SAMBA [53], and cMonkey [54].

Semisupervised Clustering

In unsupervised clustering no prior information is given; the data points are clustered into disjoint sets using the similarity information. In many cases a small amount of information is available about the data points. The information can be in the form of pairwise (*must-link* or *cannot-link*) constraints, which define the relationship between the data points [55]. A must-link constraint specifies that the two data points should be assigned to the same cluster. A cannot-link constraint specifies that the two data points should not be assigned to the same cluster. The information can also be about the class labels for some points or all points with a reliability level [56]. The process of clustering using a side information is called semisupervised clustering. The set of extra information provides a limited supervision but guides the clustering process. Examples of semisupervised clustering algorithm include *COP-Kmeans* [55], and *PCKmeans* [57].

DISPERSION STATISTICS FOR CLUSTERING

The partitioning (3) of the data points $\mathbf{x}_i$ (which are the rows of the $N \times p$ data matrix D of Equation (2)), gives rise to the $p \times p$ total dispersion matrix,

$$T = \sum_{k=1}^K \sum_{\mathbf{x}_i \in C_k} (\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})', \quad (24)$$

where the p -dimensional vector $\bar{\mathbf{x}}$ is the mean of all the data points. The total dispersion matrix T can be partitioned as

$$T = W + B, \quad (25)$$

where W is the *within-cluster dispersion matrix*,

$$W = \sum_{k=1}^K \sum_{\mathbf{x}_i \in C_k} (\mathbf{x}_{ik} - \bar{\mathbf{x}}_k)(\mathbf{x}_{ik} - \bar{\mathbf{x}}_k)' \quad (26)$$

here $\bar{\mathbf{x}}_k$ is the mean of the data points in the cluster C_k , and B is the *between-clusters dispersion matrix*,

$$B = \sum_{k=1}^K N_k (\bar{\mathbf{x}}_k - \bar{\mathbf{x}})(\bar{\mathbf{x}}_k - \bar{\mathbf{x}})', \quad (27)$$

where N_k is the number of data points in C_k .

For univariate data ($p = 1$), Equation (25) represents the division of the total sum of squares of a variable into the within- and between-clusters sum of squares. In the univariate case, a natural criterion for grouping would be to choose the partition corresponding to the minimum value of the within-group sum of squares or, equivalently, the maximum value of the between-cluster sum of squares.

In the multivariate case ($p > 1$) the derivation of a clustering criterion from the Equation (25) is not as clear-cut as the univariate case, and several alternatives have been suggested.

DISPERSION OBJECTIVES

The dispersion statistics of the section titled "Dispersion Statistics for Clustering" suggest several different objectives for clustering.

Minimization of trace (W)

The trace of the matrix W in Equation (26) is the sum of the within-cluster variances. Minimizing this trace works to make the clusters more homogeneous; thus the problem,

$$\min\{\text{trace } W\}, \quad (28)$$

which, by Equation (25) is equivalent to

$$\max\{\text{trace } B\}. \quad (29)$$

This can be shown to be equivalent to minimizing the sum of the squared Euclidean distances between data points and their cluster mean, which is used in k -means algorithms. The criterion can also be derived on the basis of the distance matrix:

$$E = \sum_{k=1}^K \frac{1}{2N_k} \sum_{i=1}^{N_k} \sum_{j=1, j \neq i}^{N_k} d_{ij}^2, \quad (30)$$

where d_{ij} is the Euclidean distance between i th and j th data points in cluster C_k . Thus the minimization of $\text{trace}(W)$ is equivalent to the minimization of the homogeneity criterion $h_1(C_k)/N_k$ for Euclidean distances and $n = 2$ [58].

Minimization of $\det(W)$

The differences in cluster mean vectors are based on the ratio of the determinants of the total and within-cluster dispersion matrices. Large values of $\det(T)/\det(W)$ indicate that the cluster mean vectors differ. Thus, a clustering criterion can be constructed as the maximization of this ratio

$$\min \left\{ \frac{\det(T)}{\det(W)} \right\}. \quad (31)$$

Since T is the same for all partitions of N data points into K clusters, this problem is equivalent to

$$\min\{\det(W)\}. \quad (32)$$

Maximization of $\text{trace}(BW^{-1})$

A further criterion considered is a combination of dispersion matrices:

$$\max \left\{ \text{trace} \left(\frac{B}{W} \right) \right\}. \quad (33)$$

This criterion is obtained from the product of the between-clusters dispersion matrix and the inverse of the within-clusters dispersion matrix. This function is also a further test criterion used in the context of multivariate analysis of variance, with large values of $\text{trace}(BW^{-1})$ indicating that the cluster mean vectors differ.

Comparison of the Clustering Criteria

The criterion (31) is, perhaps, the most commonly used one among the three clustering criteria presented above. However, it has some serious problems [58]. First, the method is not scale invariant. This means that, different solutions may be obtained from the

raw or standardized data. Clearly, this is of considerable practical importance because of the need for standardization in many applications. Another problem with the use of this criterion is that it may impose a *spherical* structure on the observed clusters even when the natural clusters in the data are of other shapes. The criteria in Equations (28) and (31) are not affected by scaling. Moreover, the criterion in Equation (32), which has also been widely used does not restrict clusters to being spherical. It can also identify *elliptical* clusters. However, this criteria assumes that all clusters in the data have the same shape. Finally, both the criteria in Equations (28) and (32) produce clusters that are of nearly equal size, meaning that clusters contain roughly equal numbers of data points.

COGNITIVE MAPPING AND STRATEGIC OPTIONS DEVELOPMENT AND ANALYSIS (SODA)

ION GEORGIU

Departamento de Informatica e
Metodos Quantitativos, Escola de
Administração de Empresas de
São Paulo, São Paulo,
São Paulo, Brazil

The usefulness of cognitive mapping has gained currency since the mid-1980s [1–7]. A number of variants exist. Social science methodology, in conjunction with information visualization, has put forward concept mapping [8]. The Florida University System incorporates the Institute for Human and Machine Cognition which has devised, and made freely available, the *Cmap tools* program that “empowers users to construct, navigate, share, and criticize knowledge models represented as concept maps” (see <http://www.ihmc.us/>). A string of mind-mapping gurus has emerged, the most famous being Tony Buzan, the self-proclaimed “inventor of mind mapping” ([9]; <http://www.imindmap.com>). Furthermore, irrespective of whether one calls them concept maps, cognitive maps, or mind maps, particular structures have spawned spidergrams, bubble diagrams, logic diagrams, and tree diagrams (to name but a few). Clearly, cognitive mapping is a flourishing industry, one that is driven by a market demand for such tools.

Strategic options development and analysis, or SODA, is one of the most prominent problem structuring methods (PSMs) developed in British operational research [10–13]. As with all PSMs, SODA is used for group decision making in situations characterized by nontrivial uncertainty and complexity that is not amenable to formal algorithmic modeling [14–17]. SODA incorporates a particular version of cognitive mapping as its main tool. The process of designing SODA

maps, as well as their content, offer the users a transparent interface through which they can explore, learn about, and consequently take more confident decisions to improve, or otherwise change, a problematic situation. Although mainly applied in group decision making situations, SODA has also been applied to the analysis of documents [18,19].

What differentiates SODA’s cognitive mapping approach is its basis in George Kelly’s psychological theory of personal constructs [20–22]. Although SODA does not pretend to appropriate Kelly’s theory *en masse*, it does borrow two key ideas: one theoretical and one procedural.

THEORETICAL APPROACH OF SODA

George Kelly’s theory is highly developed, so much so that there are international journals, such as the *International Journal of Personal Construct Psychology*, dedicated singularly to his psychological approach. As the title of his theory indicates, Kelly’s central theme is the manner in which human beings understand the world through mental *constructs*. Unlike a concept, a construct is dichotomously comprised of two poles, the relationship between them being one of contrast or alternative-ness. The use of binary oppositions to facilitate the elicitation of meaning was especially prominent in semiotics and linguistics during the first half of the twentieth century when Kelly was developing his theory. By the time he completed it, the semiotician Greimas [23] had begun his studies on the “semiotic square” that allowed for two simultaneous oppositions, each of which occupied the corner of a square. Although developments such as this one have been found to elicit richer understandings than a bipolar concentration [24], Kelly’s theory continues to attract attention, not least due to its perceived philosophical richness [25] and psychotherapeutical relevance [26].

George Kelly was interested in uncovering the meaning behind what people say so as

to minimize ambiguity. He noted that problems tended to be analyzed or interpreted according to the type of analyst one consulted. So, for example, if one took a problem to a Freudian analyst, it would be structured and analyzed according to Freudian principles. A behaviorist, in turn, would most probably analyze the situation and draw conclusions in terms of conditioning. All of this implies that the frame of reference of the analyst delimits what is perceived, how it is described, and what the ultimate prescription might be. Kelly's objective was to devise a theory, coupled with an analytical technique, which would remove—as far as possible—the analyst's frame of reference and so undertake problem description and resolution from the client's/patient's point of view.

This implies a significant change in the role of the analyst. The analyst, once perceived as some type of specialist in the contents of the mind, was now a process facilitator specializing in structuring the client's thoughts as the client sees them. This view of analysis and of the role of the analyst underpins SODA: what clients need is help in structuring complex perceptions so that clients themselves, with facilitative assistance, can resolve the problem using this structure.

Kelly developed a number of intricate analytical tools for his theory, the most famous of which is the repertory grid [27,28]. SODA does not use such tools [29]. The maps designed through SODA, however, are models whose essential structure is that of a graph (nodes and links) or, more exactly, a directed graph (also known as a digraph) [30,31]. As such, SODA maps are amenable to the powerful analytical tools of digraph theory [32–36], as well as givens–means–ends analysis [7]. SODA maps have also served as a basis for the design of system dynamics models [37–42].

PROCEDURE OF BIPOLAR CONSTRUCT DESIGN

SODA adheres to bipolar construct design, making for a *construct* mapping methodology, as opposed to one that involves concept mapping. The reason for this is that, for SODA,

language is the basic currency that gives meaning to people's concerns but it is also a problematic one. Language consists of words, many of which can have multiple connotations. One manner of minimizing the breadth of interpretation is to offer an alternative word or phrase that can serve to highlight what is meant by the description originally given [28, p. 11]. Say, for example, that a person is described as *pleasant*. In itself, this description is vague, not only because the term *pleasant* has numerous synonyms that open up a field of subtle variations in understanding, but because no alternatives have been put forth against which the meaning of *pleasant* can be deduced. To offer a strictly negative alternative, moreover, such as “not pleasant,” is rather useless in trying to understand what is being meant. Is the person pleasant in the sense that they are polite, or charming, or alluring, or perhaps gentle? Or is the person pleasant as opposed to being rude or perhaps exciting? A more precise alternative is required in order to obtain at least the flavor of what is meant, and this is the function of constructs. Constructs are designed with two poles, whereby the second pole serves to clarify what is meant by the first pole. For instance, to say that the person is pleasant as opposed to alluring, or pleasant as opposed to rude, already offers more precise meanings in each case. SODA would write such constructs as follows:

person is pleasant . . . person is alluring
person is pleasant . . . person is rude

The three dots serve to distinguish the two poles of a construct. The alternative pole in each case serves to contextualize and refine the understanding of the primary pole. In essence, then, the deduction or elicitation of secondary poles is crucial to the use of SODA. In practice, of course, people do not talk or write in constructs, and pushing them for alternative poles can quickly become tedious. Often, secondary poles are deduced by a SODA mapper and clarified later by the client. At times, simple negatives are used due to insuperable ambiguities. In other cases, they are left out altogether but, as will be discussed, this does not do justice to SODA as a distinct methodology.

In summary, SODA dissects an actor's oral or written description and translates it into a set of bipolar constructs. The constructs are then causally connected in a manner that reflects the actor's descriptive logic. When complete, the map can be read independently of its sources. SODA offers a qualitative, bipolar, cartographic approach to complex situations that is amenable to quantitative analysis and simulation modeling.

UNDERSTANDING SODA MAPS

Figure 1 is a SODA map *about* SODA mapping. In considering it, one can therefore appreciate both, the nature of SODA maps, as well as how to read them. To begin with, note the following:

- The numbering of constructs is purely random and serves only to reference them (they will be referenced in italics throughout this article).
- The arrows or links come with a negative sign, or are otherwise unsigned.
 - An unsigned link between two constructs indicates that their respective

primary or secondary poles are to be read in order, from the arrow's tail to the arrow's head.

- An arrow signed with a negative symbol ("–") indicates that, at that point, one must switch poles when following the argument along the link.

As an illustration, begin at construct 3 of Fig. 1 and follow the links through constructs 4, 2, 12, 6, ending at construct 8. An actor attempts to explain a problematic situation, but the description offered is not easy to follow (3). The complexity and uncertainty of the situation inhibit the actor from articulating a logical train of thought, resulting in a storm of information, a tornado of thought, so to speak (4). There is a need to impose some sort of methodological structure on the information offered by the actor (2), calling for a methodologically guided manipulation of the actor's description (12)—in this case, the use of SODA mapping. Through such methodological manipulation, knowledge of the situation is seen in a new light (6).

Note that this reading began by considering the primary pole of construct 3 and

Figure 1. Understanding SODA through a SODA map.

continued by referring to the primary poles of subsequent constructs, the reason being that the arrows in the sequence are unsigned. Due to the negative arrow between constructs 6 and 8, however, there is a switch from the primary pole of construct 6 to the secondary pole of construct 8: as long as knowledge of the situation is seen in a new light (6), the SODA map is more useful (8). If, on the other hand, there is less new insight emerging (secondary pole of construct 6), the SODA map's usefulness decreases proportionally (primary pole of construct 8), or equally, the SODA map has served its purpose.

The constructs in a SODA map are typically decisions available to be taken, or consequences that may result from decisions taken. Apart from making explicit the logical dependencies between constructs, a SODA map also renders explicit the structural significance of constructs. Constructs may be structurally categorized according to certain basic types: *tails*, *heads*, *strategic options*, *implosions*, *explosions*, and *dominants*. They may also participate in *loops*.

Tails

Tails have no constructs leading into them. In the language of graph theory, they are *transmitters* whereby their in-degree is zero and their out-degree is positive [30, p. 17]. In SODA, they are otherwise known as prime causes. In Fig. 1, constructs 3, 9, 10, and 11 are tails. They indicate that SODA mapping is primarily (but not exclusively) useful when actors find difficulty in articulating their thoughts in a linear or logical manner (3), when they have a selective, as opposed to a holistic, appreciation of the situation (9), when their level of knowledge is relatively low (10), and when they have been victims of misinformation (11).

Heads

Heads have no constructs leading out of them. In the language of graph theory, they are *receivers* whereby their out-degree is zero and their in-degree is positive [30, p. 17]. They reflect objectives, outcomes, results, or consequences stemming from the dependency paths of arrows that lead into them. When

first looking at a SODA map, the heads will usually offer a good idea of what it is about. Figure 1 has only one head, construct 8, from which the user quickly infers that the figure is a map about the usefulness of SODA maps. Heads may be highlighted for emphasis (Fig. 1 encircles construct 8 in an oval). Furthermore, large maps of complex situations usually have numerous heads, indicating the requirement to address multiple, equally necessary, and at times conflicting, objectives usually measurable on different dimensions that preclude trade-offs between them.

Strategic Options

In SODA, those constructs with immediate links to a head are called *strategic options*, from which the methodology takes its name (there is no equivalent term in graph theory). They reflect the options available through which a particular result (head) may materialize or, in other words, the immediate influences that will govern which pole of the outcome will eventually happen. We find, for instance, that the usefulness of a SODA map (8) depends upon its

- providing new insight (6);
- stimulating more questions and possibilities about the problematic situation (7);
- mapping developing perspectives about a situation (1).

Due to their perceived immediate influence upon a head, strategic options may also be emphasized diagrammatically (Fig. 1 has employed rounded rectangles).

Implosions

Implosions are constructs with a relatively high number of constructs leading directly into them. In the language of graph theory, they have a relatively high in-degree or *in-bundle* [30, p. 17]. Social network analysis [43, p. 202], with regard to directed networks (i.e., digraphs), would say that such constructs have *degree prestige* that is relatively higher to other constructs. An implosion indicates a major effect. It

is a construct affected by multiple other constructs and, by extension, multiple areas of the map. It is where a number of issues culminate or converge. In Fig. 1, construct 5 has an in-degree of four, while the only other construct that comes close is the head (8) with in-degree of three. The implosion of construct 5 serves to highlight the factors that lead to an actor's arbitrary, skewed, and unreliable understanding of a situation: the actor's limited experience (9), incognizance (10), and misinformation (11), as well as their set (and perhaps inflexible) perspective (1).

Explosions

Explosions are constructs with a relatively high number of constructs directly leading out of them. In the language of graph theory, they have a relatively high out-degree or *out-bundle* [30, p. 17]. Social network analysis [43, p. 199], with regard to directed networks, would say that such constructs have *degree centrality* that is relatively higher to other constructs. An explosion indicates a major cause. It is a construct that affects multiple other constructs and by extension, multiple areas of the map. It is from where a number of multiple issues stem or diverge. In Fig. 1, the three strategic options (6, 7, 1) all share the same, relatively higher out-degree. To take but one example, construct 7 indicates that with the consideration of more questions and possibilities about the problematic situation, the usefulness of SODA maps is increased (8), and an actor will be open to new perspectives (1).

Dominants

Dominants are constructs with a relatively high total number of constructs leading into them and leading out of them. In the language of graph theory, they have a relatively high degree (sum of in-degree and out-degree) [30, p. 17]. Social network analysis [43, p. 173], with regard to the *underlying graph* of the digraph [44, p. 92], would call such constructs *central*. A construct with a relatively high degree indicates cognitive centrality of an issue in an actor's perceptions, and/or central relevance of an issue to the situation in question. Depending on the

balance between in-degree and out-degree, a dominant will affect, and be affected by, multiple constructs and by extension, multiple areas of the map. Whereas heads offer a good initial idea of what a map is about, dominants offer a good indication of the major issues that must be tackled in order to reach the heads. In Fig. 1, construct 5 has the highest degree of the map. It indicates that a major issue in judging the usefulness of SODA maps is their ability to render actors' perspectives less arbitrary and more reliable.

Loops

In SODA, loops are not to be confused with the manner in which this term is understood in digraphs. The equivalent term in digraph theory would be *cycles* [44, p. 95]. In SODA, moreover, loops are of primary interest for identifying feedback dynamics.

It is difficult to perceive feedback dynamics mentally, without the aid of some interface that renders them explicit. And yet, it is exactly such dynamics that can sabotage an otherwise seemingly logical set of decisions. The identification and analysis of feedback loops in any map is therefore important. More ominously, feedback loops can serve to identify areas of uncontrolled degenerative or regenerative dynamics, pointing to the ultimate collapse of the situation under consideration.

To begin with, consider the relatively more benign case of a loop that is self-controlled. This occurs when a loop contains an odd number of negative links. Any perturbation in the state of the variables within the loop will result in stabilizing dynamics to bring activity under control, not unlike a thermostat. This can be illustrated in a simple decision making situation faced by a bus company at various times of the day, such as that depicted in Fig. 2. Here, as the number of passengers per bus increases (17), the pressure to service the route increases (18), thus the decision is taken to make more buses available on the route (19). Eventually, and due to the availability of more buses, the number of passengers per bus decreases (17), easing the service pressure (18), and thus leading the company to reduce the number of buses on the route (19). Of course, as the

Figure 2. Self-controlled feedback loop.

number of passengers picks up again (17), the company will eventually find itself needing to make available more buses (19). There is a seemingly regular swing between making available more or fewer buses, a swing controlled by the effects on service pressure (18).

This pendulum effect is also apparent in Fig. 1. Beginning from the primary pole of construct 6 and reading through to constructs 7, 1, 5, 4, 2, and 12, leads to the secondary pole of construct 6, and ultimately to SODA maps being less useful (8). Remaining in the same circuit but now beginning with the secondary pole of construct 6, will result in SODA maps being more useful. Indeed, from this loop, one can also infer that the usefulness of a SODA map (8) is a function of the dynamic interrelations between three issues: the provision of insight (6, 7), the state of an actor's understanding (1, 5, 4, 2), and the methodological manipulation afforded by the approach (12).

Self-controlled loops do not present problems as long as the exhibited control is desired. More problematic are those loops constituted completely by unsigned links, or by an even number of negative links. A loop with either of these characteristics suggests either generative growth or degenerative decline, depending on the poles that are followed within each construct. Figure 3 extends the bus company situation by taking into account throughput time (20), passenger satisfaction (21), and the decisions of the public to use or not to use the bus as a viable means of transportation (22). Reading

through the figure of eight, one finds that the number of buses on the route is either increasing or decreasing uncontrollably, depending on which poles are followed. Furthermore, although the bus company might like the idea of having more passengers, hence more revenues, and more growth, the feedback loop highlights that any process without controls will inevitably collapse.

An interesting aspect of Fig. 3 is the dominant construct (17) regarding the number of passengers per bus. This construct participates in two self-controlled loops, one on either side of it. When the loops are conjoined into the figure of eight, however, any controlling dynamics are cancelled out, resulting in the inevitable collapse of this situation either through uncontrolled growth or uncontrolled decline. In other words, when viewing a seemingly self-controlled loop, it is worth taking into account its wider context to ensure that it might not actually be participating in some wider and more dangerous cycle.

GROUP DECISION MAKING

If complexity and uncertainty already pose a considerable challenge for an individual decision maker, then the challenge is compounded in group decision making where different actors, with different views, and perhaps from different organizations or departments, have to work together toward a resolution that accommodates all those concerned. The classic approach of SODA under these circumstances is to begin with the design of individual actors' maps. This allows each group member to at least have a model of their own understanding of the situation. An individual map is usually designed in conjunction with a semistructured interview or discussion with the person concerned. As individual maps are designed and collected together, points of commonality between them will necessarily emerge since all the individuals concerned share the same problematic situation. These commonalities may be explicit constructs or clusters of constructs that identify similar issues. They will form the points that link one individual map to another and hence allow the emergence of a group map.

Figure 3. Uncontrolled regenerative/degenerative feedback loop.

This group map, or merged map, will not necessarily reflect how any one individual understands the situation, but will reflect the group understanding. The understanding of a group is always somewhat more abstract and difficult to grasp, and a SODA map offers a means for concretely visualizing such an understanding. It also allows each individual to perceive relationships between decisions that might otherwise have remained obscure, as well as allowing for an appreciation of the understanding of others. As such, the merged SODA map is a tool for organizational, or group, learning that enables a group to take decisions more confidently.

CRITICAL APPRECIATION

SODA is one of the most frequently used PSMs [45]. Computer software, called Decision Explorer[®], has also been designed to facilitate construction and analysis of SODA maps (see www.banxia.com). This is especially useful for the case of large maps that contain hundreds of constructs. Still, there remain significant areas for further research in SODA, especially related to graph theory, diagrammatic representation, and the use of constructs.

As mentioned earlier, recent years have seen some developments in methods for analyzing SODA maps, especially from a graph theoretical point of view. In comparison, however, to other approaches that utilize

graph theory—such as, for example, social network analysis [43]—the SODA literature indicates relatively little use of this branch of mathematics. It can be shown that SODA maps share the four primitives and four axioms of digraphs [30, p. 9]. This being the case, research needs to be carried out on the numerous graph theoretic analyses that are available, in order to uncover which ones are of special relevance to SODA analyses. More research is also required on how matrices, graph mining [46], and blockmodeling [47] can inform SODA map analyses.

The diagramming process itself has also been left largely unaddressed by SODA. Graph drawing [48] is a novel area within graph theory and an interdisciplinary excursion here will undoubtedly benefit the representational design of SODA maps. The broader field of information visualization [49–53] also offers a wealth of research, which might not only be relevant to SODA map representations in general, but also undoubtedly useful for the further development of the Decision Explorer[®] software.

A scan of the literature shows that the use of bipolar constructs in SODA mapping appears less frequently than the use of single-issue concepts. This is surprising for an approach that explicitly draws from Kelly's theory. It also does not serve to differentiate SODA very effectively from other cognitive mapping approaches. One attempt at differentiation was made in the

late 1990s whereby SODA was rechristened as “journey making” and aligned closely with strategic management [54]. In the span of 500 pages, however, the idea of a construct got short shrift and only four diagrams contained any constructs at all (see pp. 96, 287, 291, 295). Since SODA is explicitly concerned with perceptions and meanings, rather than seemingly relegating the idea of construct to the background, research would arguably be better served by exploring this idea to its limits, alongside the contributions of semiotics and perhaps even linguistics.

CONCLUSION

SODA is a cognitive mapping approach whose qualitative content is structured in such a manner as to render it especially amenable to quantitative analysis. Its diagrammatic basis makes it transparent to users, requiring relatively little prior training to understand the approach. The maps themselves offer a means for describing situations and thus facilitate learning and understanding.

The fact that maps are amenable to quantitative analysis must not be taken as in any way minimizing their qualitative content. Measurements, of any sort, do not provide answers in themselves, and much less should they be used as a substitute for thinking through the situation in question. Measurements are to be used in conjunction with a more holistic understanding of the map and the situation it is describing, so that informed conclusions can be drawn.

Furthermore, the maps should be treated less as models of cognition—that is, as psychological tools—and more as means for investigating problematic situations. For, although the perspectives of decision makers are what maps record, ultimately maps describe situations.

Finally, relatively large maps are not necessarily more complex than smaller maps. They may, for example, have no multiple and interrelated feedback loops. Complexity is not dependent on the size of any particular variable, but on the interrelationship of variables.

More generally, faced with complexity and uncertainty, and prior to any prescriptive action, a descriptive and exploratory approach is required for initiating focused debate and targeted exploration, two essentials of effective decision making. This is exactly what SODA offers.

PROPERTIES OF COHERENT SYSTEMS AT A FIXED POINT IN TIME

The first formal study of coherent systems was conducted by Birnbaum *et al.* [1], whose work led to a unified framework for analyzing an engineering system in terms of its components.

Consider a system with n components, which we will examine at a particular instant in time. For each $i = 1, \dots, n$ define x_i , the state of the i th component at that instant, by

$$x_i = \begin{cases} 1, & \text{component } i \text{ is working;} \\ 0, & \text{component } i \text{ is in failure.} \end{cases} \quad (1)$$

The state of the system depends solely on the states of its components; specifically, the system works if certain combinations of components work.

Example 1. Natvig [2] gives the following example, a power supply system represented by Fig. 1. The system works (is able to provide power) as long as it can (i) generate power, and (ii) transmit it. In Fig. 1, component 1 represents an offsite power source and components 2 and 3 are transformers; component 6, an onsite emergency generator, backs up that part of the process. Components 4, 5, and 7 are cables.

The Structure Function

We define the structure function $\phi : \{0, 1\}^n \rightarrow \{0, 1\}$ by

$$\phi(\mathbf{x}) = \begin{cases} 1, & \text{the system is working;} \\ 0, & \text{the system is in failure;} \end{cases} \quad (2)$$

where $\mathbf{x} = (x_1, \dots, x_n)$.

The two simplest systems are the *series system* and the *parallel system*. We state here the structure functions for those two cases, and also consider the *k-out-of-n system*.

A series system works if and only if all of its components work. Thus

$$\phi_{\text{series}}(\mathbf{x}) = \min \{x_1, \dots, x_n\} = \prod_{i=1}^n x_i.$$

A parallel system works if at least one of its components works:

$$\phi_{\text{parallel}}(\mathbf{x}) = \max \{x_1, \dots, x_n\} = 1 - \prod_{i=1}^n (1 - x_i).$$

Define the *cup operator* $\sqcup$ through its Boolean addition properties

$$\begin{aligned} 0 \sqcup 0 &= 0; & 0 \sqcup 1 &= 1; & 1 \sqcup 0 &= 1; \\ 1 \sqcup 1 &= 1. \end{aligned}$$

Then, for any $\mathbf{x} \in \{0, 1\}^n$,

$$\prod_{i=1}^n x_i = x_1 \sqcup x_2 \sqcup \dots \sqcup x_n = 1 - \prod_{i=1}^n (1 - x_i)$$

and thus, we can write $\phi_{\text{parallel}}(\mathbf{x}) = \prod_{i=1}^n x_i$.

A *k-out-of-n system* works if and only if at least k of its components work. For example, the structure function for a two-out-of-three system can be written as

$$\phi(\mathbf{x}) = (x_1 x_2) \sqcup (x_1 x_3) \sqcup (x_2 x_3).$$

Note that the *k-out-of-n system* includes the series (*n-out-of-n*) and parallel (*one-out-of-n*) systems as special cases.

Figure 1. Power supply system for Example 1, taken from Ref. 2. System works if and only if there is a working connection from S to T .

Example 2. The structure function for Natvig's [2] power supply system of Example 1 is given by

$$\phi(\mathbf{x}) = (x_1(x_2 \sqcup x_3)(x_4 \sqcup x_5)) \sqcup (x_6x_7).$$

Path and Cut Sets

In this section, we develop a representation of the structure function based on the identification of subsets of the components whose (non-) failure guarantees the system's (non-) failure; see also Ref. 3, Section 1.3, or 4.

Given a system of n components with structure function ϕ , the vector $\mathbf{x} \in \{0, 1\}^n$ is called a *path vector* if $\phi(\mathbf{x}) = 1$, and a *cut vector* if $\phi(\mathbf{x}) = 0$. Define

$$C_1(\mathbf{x}) = \{i : x_i = 1\} \text{ and } C_0(\mathbf{x}) = \{i : x_i = 0\}.$$

If $\mathbf{x}$ is a path vector, $C_1(\mathbf{x})$ is the corresponding *path set*; if $\mathbf{x}$ is a cut vector, $C_0(\mathbf{x})$ is the corresponding *cut set*.

We say that $\mathbf{x}$ is a *minimal path vector* if $\phi(\mathbf{x}) = 1$ and $\phi(\mathbf{y}) = 0$ for any $\mathbf{y}$ such that each $y_i \leq x_i$ with strict inequality for some i . Similarly, $\mathbf{x}$ is said to be a *minimal cut vector* if $\phi(\mathbf{x}) = 0$ and $\phi(\mathbf{y}) = 1$ for any $\mathbf{y}$ satisfying $y_i \geq x_i$ for each i , with strict inequality for some i . Thus, a minimal path vector represents a state in which the system works, but for which the failure of even a single working component would cause system failure. A minimal cut vector represents a failure state in which the repair of even a single non-working component would lead to the system working. If $\mathbf{x}$ is a minimal path vector, $C_1(\mathbf{x})$ is called a *minimal path set*; if $\mathbf{x}$ is a minimal cut vector $C_0(\mathbf{x})$ is called a *minimal cut set*.

Denote the minimal path sets of a system by $\mathcal{P}_1, \dots, \mathcal{P}_r$, and the minimal cut sets by $\mathcal{C}_1, \dots, \mathcal{C}_s$. Then the system is working if and only if the components of at least one minimal path set are all working. We can then write

$$\phi(\mathbf{x}) = \bigsqcup_{j=1}^r \prod_{i \in \mathcal{P}_j} x_i. \quad (3)$$

Similarly, the system is working if and only if at least one component from each minimal cut set is working, thus

$$\phi(\mathbf{x}) = \prod_{j=1}^s \bigsqcup_{i \in \mathcal{C}_j} x_i. \quad (4)$$

Example 3. Consider the power supply system from Example 1. From Fig. 1, the minimal path sets of this system are easily seen to be

$$\mathcal{P}_1 = \{1, 2, 4\}; \quad \mathcal{P}_2 = \{1, 2, 5\}; \quad \mathcal{P}_3 = \{1, 3, 4\}; \\ \mathcal{P}_4 = \{1, 3, 5\}; \text{ and } \mathcal{P}_5 = \{6, 7\}.$$

The minimal cut sets for this system are given by

$$\mathcal{C}_1 = \{1, 6\}; \quad \mathcal{C}_2 = \{1, 7\}; \quad \mathcal{C}_3 = \{2, 3, 6\}; \\ \mathcal{C}_4 = \{2, 3, 7\}; \quad \mathcal{C}_5 = \{4, 5, 6\}; \text{ and } \mathcal{C}_6 = \{4, 5, 7\}.$$

The reader can verify that both Equations (3) and (4) return the expression given in Example 2.

Coherence

Define

$$(1_i, \mathbf{x}) = (x_1, \dots, x_{i-1}, 1, x_{i+1}, \dots, x_n)$$

and

$$(0_i, \mathbf{x}) = (x_1, \dots, x_{i-1}, 0, x_{i+1}, \dots, x_n).$$

Then for any fixed $i = 1, \dots, n$, a structure function ϕ can be expressed as

$$\phi(\mathbf{x}) = x_i \phi(1_i, \mathbf{x}) + (1 - x_i) \phi(0_i, \mathbf{x}).$$

This representation is known as the *pivotal decomposition* of a structure function.

Definition 1. The i th component of a system with structure function ϕ is *irrelevant* if $\phi(1_i, \mathbf{x}) = \phi(0_i, \mathbf{x})$ for all $\mathbf{x}$. Otherwise the i th component is said to be *relevant*.

Definition 2. A structure function is said to be *monotone* if for any $\mathbf{x}$ and $\mathbf{y}$ such that $x_i \leq y_i$ for each $i = 1, \dots, n$, $\phi(\mathbf{x}) \leq \phi(\mathbf{y})$.

Thus, a component is relevant when there exists at least one case where the state of the system depends on whether the component is working or in failure, and a structure function is monotone when the state of the system can never be improved by the failure of a component. We can now give a formal definition of a coherent system.

Definition 3. A system is *coherent* if each of its components is relevant and its structure function is monotone.

A coherent system consists of components that when working, never harm the system and improve the system in at least one instance. Thus, each working component is beneficial to the system. It is quite rare to find a structure of components designed in practice that is not coherent. For this reason, the study of engineering systems can be narrowed to the study of coherent systems.

For a system of $n = 3$ components, there are five coherent structures. We have encountered three already, in the series, parallel, and two-out-of-three systems. Two more coherent systems are given by $\phi(\mathbf{x}) = x_1 \bigcup (x_2 x_3)$ and $\phi(\mathbf{x}) = x_1 (x_2 \bigcup x_3)$. For a system of $n = 4$ components, there are 20 possible coherent structures. A general rule for the number of coherent systems of n components remains an open question.

We now take up the question of comparison between two coherent systems of n components. It seems reasonable to declare system B with structure function ϕ_B better than system A with structure function ϕ_A if $\phi_A(\mathbf{x}) \leq \phi_B(\mathbf{x})$ for all $\mathbf{x} \in \{0, 1\}^n$, with a strict inequality for at least one $\mathbf{x}$. In other words, system B is better than system A if it works

in all the instances where system A works, and at least one case where system A does not. The following theorem asserts that all coherent systems fall somewhere between the series system and the parallel system by this standard.

Theorem 1. For any coherent system in n components with structure function ϕ ,

$$\prod_{i=1}^n x_i \leq \phi(\mathbf{x}) \leq \bigcup_{i=1}^n x_i \quad (5)$$

for any $\mathbf{x} \in \{0, 1\}^n$.

Proof. Define $\mathbf{0} = (0, \dots, 0)$ and $\mathbf{1} = (1, \dots, 1)$. All coherent systems have the property that $\phi(\mathbf{0}) = 0$ and $\phi(\mathbf{1}) = 1$. To prove Relation (5) we must consider three cases.

1. If $\prod x_i = 1$, then $\bigcup x_i = 1$ and $\mathbf{x} = \mathbf{1}$. Since $\phi(\mathbf{1}) = 1$, Relation (5) holds.
2. If $\bigcup x_i = 0$, then $\prod x_i = 0$ and $\mathbf{x} = \mathbf{0}$. Since $\phi(\mathbf{0}) = 0$, Relation (5) holds.
3. If $\prod x_i = 0$ and $\bigcup x_i = 1$, then Relation (5) reduces to $0 \leq \phi(\mathbf{x}) \leq 1$ and holds trivially.

The Reliability of a System

Up to this point, we have conducted only a deterministic analysis of coherent systems, in which the system in question is either working or not, depending on the states of its components. Beginning here and continuing in the next section, we take up a probabilistic study of coherent systems, wherein the component states, and the state of the system, are treated as random variables. Still holding time fixed, we consider a coherent system of n components, and let p_i denote the probability that the i th component is working for $i = 1, \dots, n$; let $\mathbf{p} = (p_1, \dots, p_n)$. We denote the state of component i by X_i , defined identically to Equation (1), but using capital-letter notation to indicate the stochastic nature of X_i . The state of the system is indicated by the random variable $\phi(\mathbf{X})$, where ϕ is again the structure function defined by Equation (2), now taking as its argument the random vector $\mathbf{X} = (X_1, \dots, X_n) \in \{0, 1\}^n$.

Our first goal is to study the probability that the system works as a function of the probabilities that the individual components work.

Definition 4. The *reliability function* of a coherent system ϕ is a mapping $h_\phi : [0, 1]^n \rightarrow [0, 1]$ defined by $h_\phi(\mathbf{p}) = \Pr(\phi(\mathbf{X}) = 1)$.

Assume the component states are stochastically independent, so the X_i are independent Bernoulli random variables with success probabilities p_i for $i = 1, \dots, n$. The state of the system $\phi(\mathbf{X})$ is likewise a Bernoulli random variable, with success probability $h_\phi(\mathbf{p})$. The reliability function of a series system is given by

$$\begin{aligned} h_{\text{series}}(\mathbf{p}) &= \Pr(\phi_{\text{series}}(\mathbf{X}) = 1) = \Pr\left(\prod_{i=1}^n X_i = 1\right) \\ &= \Pr(X_1 = 1, \dots, X_n = 1) \\ &= \prod_{i=1}^n \Pr(X_i = 1) = \prod_{i=1}^n p_i, \end{aligned}$$

and that of a parallel system is found to be

$$\begin{aligned} h_{\text{parallel}}(\mathbf{p}) &= \Pr(\phi_{\text{parallel}}(\mathbf{X}) = 1) = \Pr\left(\bigsqcup_{i=1}^n X_i = 1\right) \\ &= \Pr\left(1 - \prod_{i=1}^n (1 - X_i) = 1\right) \\ &= \Pr\left(\prod_{i=1}^n (1 - X_i) = 0\right) \\ &= 1 - \Pr\left(\prod_{i=1}^n (1 - X_i) = 1\right) \\ &= 1 - \Pr(X_1 = 0, \dots, X_n = 0) \\ &= 1 - \prod_{i=1}^n \Pr(X_i = 0) = 1 - \prod_{i=1}^n (1 - p_i). \end{aligned}$$

Define the cup operator for a vector of probabilities analogously to our earlier definition for zeros and ones, so that $\bigsqcup_{i=1}^n p_i = 1 - \prod_{i=1}^n (1 - p_i)$. Then $h_{\text{parallel}}(\mathbf{p}) = \bigsqcup_{i=1}^n p_i$.

From these two special cases, it might be tempting to believe that $h_\phi(\mathbf{p})$ can be obtained

from $\phi(\mathbf{x})$ simply by replacing the x_i with p_i . However, this is not the case in general.

A pivotal decomposition can be defined for the reliability function. Let $h_\phi(1_i, \mathbf{p}) = \Pr(\phi(1_i, \mathbf{X}) = 1)$ and $h_\phi(0_i, \mathbf{p}) = \Pr(\phi(0_i, \mathbf{X}) = 1)$. Then,

$$\begin{aligned} \Pr(\phi(\mathbf{X}) = 1) &= \Pr(X_i = 1) \Pr(\phi(\mathbf{X}) = 1 | X_i = 1) \\ &\quad + \Pr(X_i = 0) \Pr(\phi(\mathbf{X}) = 1 | X_i = 0) \\ &= p_i \Pr(\phi(1_i, \mathbf{X}) = 1) + (1 - p_i) \Pr(\phi(0_i, \mathbf{X}) = 1) \end{aligned}$$

or

$$h_\phi(\mathbf{p}) = p_i h_\phi(1_i, \mathbf{p}) + (1 - p_i) h_\phi(0_i, \mathbf{p}). \quad (6)$$

An interesting early application of this representation is attributable to Esary and Proschan [5], who called h_ϕ the *structure reliability function* and employed Equation (6) to study properties of upper and lower bounds on the system reliability for a k -out-of- n system. We will make use of Equation (6) in proving the following result.

Theorem 2. The reliability function h_ϕ of a coherent system ϕ in n independent components is strictly increasing in each p_i for all $\mathbf{p} \in (0, 1)^n$.

Proof. From the pivotal decomposition Equation (6),

$$\begin{aligned} \frac{\partial}{\partial p_i} h_\phi(\mathbf{p}) &= h_\phi(1_i, \mathbf{p}) - h_\phi(0_i, \mathbf{p}) \\ &= \Pr(\phi(1_i, \mathbf{X}) = 1) - \Pr(\phi(0_i, \mathbf{X}) = 1). \end{aligned}$$

Since ϕ is monotone in each component, $\phi(1_i, \mathbf{x}) \geq \phi(0_i, \mathbf{x})$ for all $\mathbf{x}$, and thus $\Pr(\phi(1_i, \mathbf{X}) = 1) \geq \Pr(\phi(0_i, \mathbf{X}) = 1)$. Thus, we have

$$\begin{aligned} \frac{\partial}{\partial p_i} h_\phi(\mathbf{p}) &\geq 0 \quad \text{for all } \mathbf{p} \in [0, 1]^n, \\ &\text{for each } i = 1, \dots, n. \end{aligned}$$

Further, since every component of ϕ is relevant, there exists for each i a case $\mathbf{x}^*$ such

that $\phi(1_i, \mathbf{x}^*) > \phi(0_i, \mathbf{x}^*)$; for any $\mathbf{p} \in (0, 1)^n$, we have

$$\Pr(\mathbf{X} = \mathbf{x}^*) = \prod_{i=1}^n p_i^{x_i^*} (1 - p_i)^{1-x_i^*} > 0.$$

Thus,

$$\frac{\partial}{\partial p_i} h_\phi(\mathbf{p}) > 0 \text{ for all } \mathbf{p} \in (0, 1)^n, \\ \text{for each } i = 1, \dots, n.$$

Each working component is beneficial to the system, so an increase in the probability that a component works necessarily increases the probability that the system works.

BEHAVIOR OF COHERENT SYSTEMS OVER TIME

We now consider system reliability as a function of time. In particular, we are interested in what can be deduced about the lifetime of a system from the probability distributions of its components' lifetimes. To that end, consider a system of n components, and let T_i denote the lifetime of component i for $i = 1, \dots, n$. We assume that the T_i are independent random variables with distribution functions $F_i(t) = \Pr(T_i \leq t)$. We denote the *survival functions* by $\bar{F}_i$, so

$$\bar{F}_i(t) = \Pr(T_i > t) = 1 - F_i(t),$$

for each $i = 1, \dots, n$.

Suppose we start the system running at time $t = 0$ with all components working, that is, we assume that each $F_i(0) = 0$. Then the i th component is still working as of time $t > 0$ if and only if its lifetime surpasses t (we assume that once a component fails, it remains in failure until the system is restarted). If we let

$$X_i(t) = \begin{cases} 1, & \text{component } i \text{ working at time } t; \\ 0, & \text{otherwise;} \end{cases}$$

then the probability that component i still works at time t is given by $p_i(t) = \Pr(X_i(t) = 1) = \bar{F}_i(t)$ for each $i = 1, \dots, n$.

Let T denote the lifetime of a coherent system with independent components, structure

function ϕ , and system reliability function h . Define $\mathbf{X}(t) = (X_1(t), \dots, X_n(t))$, and the probability that the system still works at time t is given by $\Pr(\phi(\mathbf{X}(t)) = 1) = h(p_1(t), \dots, p_n(t))$. Since the system still works at time t if and only if $T > t$, we have

$$\Pr(T > t) = h(\bar{F}_1(t), \dots, \bar{F}_n(t)),$$

an expression obtained by Esary and Proschan [5]. Thus, the system survival function $\bar{F}_T(t) = \Pr(T > t)$ depends only on the survival functions of the individual components and the reliability function of the system.

The Signature Vector

Continue to imagine we start the system running at time $t = 0$ with all components working, and suppose we observe the system until every component's failure. Here, we further assume that the individual component lifetimes are independent and identically distributed (i.i.d.) random variables, thus $F_i(t) \equiv F(t)$ for each $i = 1, \dots, n$. Let $\bar{F}(t) = 1 - F(t)$ denote the common survival function.

Let $T_{(i)}$ denote the time of the i th component failure for $i = 1, \dots, n$. Thus, $0 < T_{(1)} \leq T_{(2)} \leq \dots \leq T_{(n)}$ are the *order statistics* for the i.i.d. sample of component lifetimes. From the distribution theory for order statistics,

$$\Pr(T_{(k)} > t) = \sum_{j=0}^{k-1} \binom{n}{j} (F(t))^j (\bar{F}(t))^{n-j}.$$

We now give an alternative characterization of the survival function of a coherent system.

Definition 5. Let $\pi_k = \Pr(T = T_{(k)})$ denote the probability that the system fails at the k th failure of a component. The *signature* of a coherent system is the probability vector $\boldsymbol{\pi} = (\pi_1, \dots, \pi_n)$.

If F is continuous, then $\boldsymbol{\pi}$ does not depend on F and the system survival function can be written as

$$\begin{aligned}
\bar{F}_T(t) &= \sum_{k=1}^n \Pr(T = T_{(k)}) \Pr(T > t | T = T_{(k)}) \\
&= \sum_{k=1}^n \pi_k \Pr(T_{(k)} > t) \\
&= \sum_{k=1}^n \sum_{j=0}^{k-1} \pi_k \binom{n}{j} (F(t))^j (\bar{F}(t))^{n-j}. \quad (7)
\end{aligned}$$

This representation, first given by Samaneigo [6], was recently extended to systems with exchangeable components by Navarro and Rychlik [7] and Navarro *et al.* [8].

Consider a coherent system of $n = 3$ components. We noted above that there are five such systems. Here, we will derive the signature of each.

1. If the system components are in series, so $\phi(\mathbf{x}) = x_1 x_2 x_3$, then the system fails at exactly the time of the first component failure. Thus $T = T_{(1)}$ with probability 1 and thus, $\pi = (1, 0, 0)$.
2. If the components are in parallel, so $\phi(\mathbf{x}) = x_1 \sqcup x_2 \sqcup x_3$, the system works until the last component failure. Here $T = T_{(3)}$ with probability 1 and thus, $\pi = (0, 0, 1)$.
3. The two-out-of-three system $\phi(\mathbf{x}) = (x_1 x_2) \sqcup (x_1 x_3) \sqcup (x_2 x_3)$ fails at precisely the time of the second component failure; that is, $T = T_{(2)}$ with probability 1 and thus, $\pi = (0, 1, 0)$.
4. Consider $\phi(\mathbf{x}) = x_1 \sqcup (x_2 x_3)$. This system fails at the earlier of the failure of components 1 and 2 and the failure of components 1 and 3; that is, the system lifetime T satisfies

$$T = \min \{ \max(T_1, T_2), \max(T_1, T_3) \}.$$

Thus, the system is certain to still be running at the first component failure, and will survive until the third component failure if the two to fail are components 2 and 3. The signature vector for this system is $\pi = (0, \frac{2}{3}, \frac{1}{3})$.

5. Consider $\phi(\mathbf{x}) = x_1(x_2 \sqcup x_3)$, a system that fails at the earlier of the failure of component 1 and the failure of both

components 2 and 3. Here we have

$$T = \min \{ T_1, \max(T_2, T_3) \}.$$

This system will survive the first component failure if that failure is component 1, but it cannot possibly survive the second. The signature vector is $\pi = (\frac{1}{3}, \frac{2}{3}, 0)$.

For the signature vectors of the 20 coherent systems of $n = 4$ components, see Ref. 9. A nice review of the applications of signatures is given by Kochar *et al.* [10]; for a book length treatment of the subject, the reader is referred to Ref. 11.

Stochastic Ordering of Coherent Systems

The signature vector leads to a method for comparison of two coherent systems. Let T_A and T_B denote the system lifetimes for systems A and B, respectively, and define their survival functions $\bar{F}_A(t) = \Pr(T_A > t)$ and $\bar{F}_B(t) = \Pr(T_B > t)$. We say that T_A is stochastically less than or equal to T_B , and write $T_A \leq^{st} T_B$, if $\bar{F}_A(t) \leq \bar{F}_B(t)$ for all $t > 0$. Thus if systems A and B are both started at time $t = 0$, then at any point in time, the probability that system B is still running is never less than the probability that system A is still running.

A deterministic ordering between two coherent systems guarantees a stochastic ordering of the system survival times, that is, if $\phi_A(\mathbf{x}) \leq \phi_B(\mathbf{x})$ for all $\mathbf{x} \in \{0, 1\}^n$, then $T_A \leq^{st} T_B$. The following theorem gives a sufficient condition for the stochastic ordering of system lifetimes in terms of their respective signatures.

Theorem 3. *Let A and B be two coherent systems of n components each, with common component-wise distribution function F and survival function $\bar{F}$. Denote the signature vectors of systems A and B by $\pi^A = (\pi_1^A, \dots, \pi_n^A)$ and $\pi^B = (\pi_1^B, \dots, \pi_n^B)$, respectively. If*

$$\sum_{k=j}^n \pi_k^A \leq \sum_{k=j}^n \pi_k^B \text{ for each } j = 1, \dots, n,$$

then $T_A \leq^{st} T_B$.

Proof. From Equation (7),

$$\begin{aligned}
\bar{F}_A(t) &= \sum_{k=1}^n \sum_{j=1}^{k-1} \pi_k^A \binom{n}{j} (F(t))^j (\bar{F}(t))^{n-j} \\
&= \sum_{j=0}^{n-1} \left(\sum_{k=j+1}^n \pi_k^A \right) \binom{n}{j} (F(t))^j (\bar{F}(t))^{n-j} \\
&\leq \sum_{j=0}^{n-1} \left(\sum_{k=j+1}^n \pi_k^B \right) \binom{n}{j} (F(t))^j (\bar{F}(t))^{n-j} \\
&= \sum_{k=1}^n \sum_{j=0}^{k-1} \pi_k^B \binom{n}{j} (F(t))^j (\bar{F}(t))^{n-j} \\
&= \bar{F}_B(t),
\end{aligned}$$

and thus $T_A \leq^{st} T_B$.

Denote the five coherent systems for $n = 3$ components by A, B, C, D, and E in the order considered in the section titled “The Signature Vector,” so that A corresponds to three components in series, B corresponds to three components in parallel, C is the two-out-of-three case, and so on. Using Theorem 3, it is easy to verify the stochastic ordering

$$T_B \leq^{st} T_E \leq^{st} T_C \leq^{st} T_D \leq^{st} T_A.$$

Of course, it is not always possible to establish such a relationship between two coherent systems, as the following example from Kochar *et al.* [10] illustrates. Suppose $n = 4$ and let

$$\phi_A(\mathbf{x}) = x_1 \left(x_2 \coprod x_3 \coprod x_4 \right)$$

and

$$\phi_B(\mathbf{x}) = (x_1 x_2) \coprod (x_3 x_4).$$

The signatures of these systems are given by $\pi^A = (\frac{1}{4}, \frac{1}{4}, \frac{1}{2}, 0)$ and $\pi^B = (0, \frac{2}{3}, \frac{1}{3}, 0)$. Then

$$\pi_3^A + \pi_4^A > \pi_3^B + \pi_4^B$$

but

$$\pi_2^A + \pi_3^A + \pi_4^A < \pi_2^B + \pi_3^B + \pi_4^B$$

and thus the lifetime of system B is neither stochastically greater nor stochastically

less than that of system A. Indeed, of the $\binom{20}{2} = 190$ possible pairwise comparisons among the 20 coherent systems of $n = 4$ components, in 10 cases there is not a clear-cut winner.

For more on the stochastic ordering of coherent systems, the reader is again referred to Kochar *et al.* [10], who obtain conditions to compare systems in the hazard rate and likelihood ratio orderings as well. For comparisons between systems of exchangeable component lifetimes, or systems of different numbers of components, see Navarro *et al.* [8].

COLLABORATIVE PROCUREMENT

FERYAL ERHUN

Department of Management Science and
Engineering, Stanford University,
Stanford, California

INTRODUCTION

In today's vertically disintegrated business environment, manufacturers often rely on external suppliers to provide (complex) components to produce their products. Original equipment manufacturers in the computer and communications industry outsource about 70% of their manufacturing to the electronics manufacturing services industry [1]. In the aircraft industry, Boeing has outsourced about 70% of the parts for its 787 Dreamliner while Airbus relies on subcontractors for about 50% of its A350 planes [2]. Overall, for every dollar of sales revenue, 50 cents are spent on component procurement in the US manufacturing industry [3]. It is therefore crucial that firms manage their procurement effectively to maintain a competitive edge in the market. One way of achieving this goal is to move toward collaboration in relationships that were once considered to be adversarial [4,5]:

Managing this extended network of relationships [due to outsourcing] requires more transparency, better communication, greater trust, and genuine reciprocity. In a nutshell, success in this environment will hinge heavily on shifting the customer–service provider relationship from adversarial to collaborative; from one based on procurement to one grounded in partnership. (Pat McArdle, Global Outsourcing Partner at PwC [6])

Given the impact of procurement on the bottom line, collaboration in procurement promises several potential advantages. Through collaborative procurement, planners can achieve cost reductions and increase

the efficiency of their supply chains considerably by leveraging their buying power and streamlining their procurement processes.

Cohen and Roussel [7] define collaboration as “the means by which companies within the supply chain work together toward mutual objectives through the sharing of ideas, information, knowledge, risks, and rewards.” There are two key aspects of this definition. First, collaboration requires common goals. Unless everyone involved benefits from the collaboration, one cannot talk about a true collaboration. Secondly, companies should work together to achieve these common goals, which involves sharing not only the benefits but also the risks.

Collaboration can occur among different functionalities of an enterprise (i.e., *intra-enterprise collaboration*) or among independent companies, shifting the nature of their relationship from adversarial to collaborative (i.e., *inter-enterprise collaboration*); it can also occur among multiple entities (different departments of an enterprise or different enterprises), which are responsible for the same function and may potentially have conflicting objectives (i.e., *horizontal collaboration*) or among different functional areas within an enterprise or a supply chain (i.e., *vertical collaboration*) [4]. Next, we discuss collaborative procurement in the context of this classification (Fig. 1).

Intra-Enterprise Horizontal Collaborative Procurement. Within an enterprise, centralizing procurement has many advantages; for example, it reduces duplication of effort, potentially decreases the number of suppliers in the supply base and enhances the relationships with suppliers, leverages the buying power, decreases costs through scale economies (such as quantity/volume discounts or logistics consolidation), and improves inventory control through risk pooling by aggregating forecasting and procurement of different business units within an enterprise.

Vertical	• Coordinates procurement decisions with other functional areas • Eliminates inefficiencies due to silo planning	• Enables information sharing between supply chain partners • Eliminates inefficiencies due to decentralization • Enables firms to focus on their core competencies
Horizontal	• Reduces duplication of effort • Decreases the size of supply base • Enhances relationships with suppliers • Leverages buying power • Enables scale economies • Enables risk pooling	• Leverages buying power • Enables scale economies • Standardizes purchasing process • Enables firms to focus on their core competencies
	Intra-enterprise	Inter-enterprise

Figure 1. Advantages of different facets of collaboration.

As a result, significant cost savings can be realized through centralization. For example, IBM “reinvented” its purchasing by centralizing its procurement and setting up commodity councils:

Commodity councils that leverage IBM purchases worldwide have resulted in IBM sourcing parts at pricing that’s 5%–10% below industry averages. By developing close relationships with suppliers, IBM has been successfully guaranteed supply of leading-edge parts to its line of PCs, servers, workstations, and mainframes. IBM’s Internet initiative with suppliers saved the company \$70 million [in 1998] and is expected to save \$240 million [in 1999] by making the procurement process more efficient. The strategies employed have had a big impact on IBM, which [in 1998] spent about \$41.5 billion with suppliers. IBM executives say procurement has saved Big Blue hundreds of million of dollars over the past several years and helped IBM return to profitability after some near-ruinous years earlier in the decade when it was bleeding red ink [8].

Intra-Enterprise Vertical Collaborative Procurement. The purchasing department’s goal in many companies is to procure goods at minimum cost. However, this focus on cost may do more harm than good:

Grackin [Managing Director of the Supply Chain Intelligence Service of Marsh Inc.] often sees a disconnect between procurement and logistics. The first is out to secure the cheapest parts regardless of location, while the second must deal with the realities of transportation, such as port congestion. Often the savings derived from buying the lowest-price part will be more than offset by higher transportation costs [9].

Silo planning is a common practice and procurement is especially prone to its effects. Intra-enterprise vertical collaboration breaks silo planning by enabling a “net landed cost” approach. It eliminates inefficiencies by coordinating procurement decisions with other functional areas, such as manufacturing, planning, inventory control, and logistics, and by introducing common goals for these different functionalities [10]:

In late 2003, Aetna’s senior management sent down the mandate—reduce selling, general and administrative (SG&A) expenses through a more integrated spend-management program. . . . One area where the spend analysis was most effective was in legal services, “a silo that traditionally procurement was not invited

into.” . . . While the measures [a more in depth and formalized RFP (Request for Proposal) process, caps on reimbursable expenses, etc.] were initiated in the third quarter of [2004], Aetna began to see the positive results by the end of 2004. Legal services realized an overall savings of 10% by the end of 2004, with some silos within legal services achieving 30–40% reductions [11].

Inter-Enterprise Horizontal Collaborative Procurement. In inter-enterprise horizontal collaborative procurement (also known as *cooperative*, *group purchasing*, or *consortium purchasing*) two or more independent organizations (potential competitors) with similar products or services join together (either formally or informally, or through an independent third party) for the purpose of combining their purchase of materials, services, and capital goods. This is not a new concept; it is commonly used in many industries, such as health-care, chemicals, telecommunications, transportation, and services. For example, in the health-care industry, group purchasing organizations (GPOs) manage about 70–80% of the purchases that hospitals make, which is around \$195 billion annually. By taking advantage of large volumes, GPOs save hospitals “between 10 to 15% off their purchasing costs” [12]. When combined with other benefits, such as cost reductions due to standardization of the purchasing process and reductions in personnel, group purchasing increases the procurement efficiency considerably:

Last year, 25 Council of Industry members signed fixed-priced supply contracts with Pepco Energy Services to collectively purchase an estimated 80,000 megawatt hours of electricity annually. Over the first eight months of 2008, the Council of Industry energy purchasing consortium has saved over \$1 million, compared to the applicable utility rates. . . . Based on current market conditions, Pepco Energy Services estimates that the

Council of Industry energy purchasing consortium will save an additional \$504,000 for a total savings of over \$1.5 million for the 2008 calendar year [13].

Inter-Enterprise Vertical Collaborative Procurement. Collaboration between buyers and suppliers, which is based on long-term purchasing relationships, has been successfully adopted by many companies in various industries. Such a collaborative relationship requires full commitment from all parties involved as well as joint efforts to develop processes to support the new relationship:

There are no quick fixes in this game, and the shared trust, honesty, integrity, and objective focus on results must be maintained over a long time frame, unimpeded by sub-optimal squeezing of carefully chosen key suppliers. The long time frame is, in essence, used for a continuing set of business process re-engineering activities in both the customer and supplier companies, where cost and value are continually enhanced. For example, the vice-president of procurement for Honda of America at the time decided to develop one of its super-supplier relationships in sheet metal parts. After analysing existing suppliers in this area, he approached a small sheet metal company run by two brothers who had the “correct attitude.” His criteria were to find a supplier that would be excellent at collaboration, trustworthy and share a mutual motivation for results. He approached the owners and took them into his firm’s internal operations, shared best practices and taught them how to develop process engineering techniques, benchmarking and rapid knowledge implementation. They continued to collaborate, share information and provide feedback to one another, which resulted in this supplier becoming one of the most competitive in the industry. After three years, the supplier had cut the costs of its materials by half, which was significant because it had previously been competitive anyway [14].

Though difficult to attain and maintain, inter-enterprise vertical collaborative procurement provides tangible benefits. For example, in an environment where 70–80% of the manufacturing costs are due to suppliers, collaborative relationships reduced Honda’s costs by 25% in the 1990s; since “many of the cost-cutting ideas that made [Accord] so successful came from suppliers” [15].

Vertical and Horizontal Collaborative Procurement. More and more enterprises combine vertical *and* horizontal approaches to procurement to improve the overall process. Electronic marketplaces, which bring buyers and suppliers together in order to create an on-line transaction platform, are commonly used for this goal and have emerged in many industries. In the aerospace industry, Exostar, which was founded in 2000 by some of the world’s largest aerospace and defense companies—BAE Systems, Boeing, Lockheed Martin, Raytheon, and Rolls-Royce—creates an on-line collaboration platform for aerospace and defense industry partners. Exostar has over 40,000 registered companies worldwide, with an annual throughput of \$38+ billion, and electronic Request for Quotations (eRFQs) of around 72,000 [16]. Covisint is another on-line platform, which was founded in 1999 by a consortium of the world’s largest automakers—General Motors, Ford Motor Company, DaimlerChrysler, Nissan, and Renault—to manage increasing costs and inefficiencies in the automotive industry through on-line collaboration. Today, the platform supports over 45,000 organizations worldwide in the global automotive, health-care, public sector, and financial services industries [17].

In the rest of this article, we will focus on horizontal collaborative procurement. We refer interested readers to different articles in this encyclopedia for the analysis of vertical collaboration. Vertical collaboration relies on trust among parties involved;

reviews of mechanisms to build trust and incentives among supply chain partners, as well as mechanisms that enable supply chain coordination, can be found in the article titled **Supply Chain Coordination** and in the section titled “Supply Chain Collaboration” in this encyclopedia. Many supply chain partners now practice collaborative methods, which are closely related to collaborative procurement, such as Collaborative Planning, Forecasting, and Replenishment (CPFR) and Vendor-Managed Inventory (VMI). These practices eliminate supply chain inefficiencies, share risks, and enable collaboration. We refer interested readers to the articles titled **Vendor-Managed Inventory** in this encyclopedia for reviews of VMI and CPFR, respectively.

QUANTITY DISCOUNTS AND HORIZONTAL COLLABORATION

One of the major benefits of horizontal collaborative procurement is reduced purchasing costs since the firm(s) can leverage its (their joint) buying power through intra-(inter-)enterprise collaboration. This is possible as suppliers often offer quantity discounts to their buyers. We provide a simple example below that highlights the role of quantity discounts in collaborative procurement.

Two manufacturers, **M1** and **M2**, are selling the same product in two different markets. The market price for the product is set as a function of the quantity each manufacturer produces as follows: $P_i = 10.5 - q_i$, where $i = 1, 2$; q_1 and q_2 are the respective production quantities of **M1** and **M2**; and P_i is the price in market i . The manufacturers procure a subcomponent from the same supplier (one subcomponent is required for every unit produced and any unused subcomponents cannot be disposed of) who offers the following all-unit quantity discount scheme with a minimum order commitment:

$$\begin{aligned} 1 < \text{order size} \leq 3 \text{ units} &\Rightarrow \text{wholesale price} \\ &= \$3/\text{unit} \end{aligned}$$

$3 < \text{order size} \leq 5 \text{ units} \Rightarrow \text{wholesale price}$
 $= \$2.25/\text{unit}$
 $5 < \text{order size} \Rightarrow \text{wholesale price}$
 $= \$2/\text{unit}$

The supplier incurs a fixed cost of $F = \$3.50$ per order independent of the order size. The manufacturers incur a production cost of c_i per unit, where $c_1 = \$1.25$ and $c_2 = \$0.50$. Owing to restrictions on batch sizes and capacities, the manufacturers can produce 2, 4, or 6 units. Assuming no collaboration between these manufacturers, how many units should each manufacturer produce to maximize her own profit?

We can formulate the problem that each manufacturer faces as follows:

$$\max_{q_i} \Pi_i(q_i) = \max_{q_i} \{(P_i - C(q_i) - c_i) \times q_i\}, \quad (1)$$

where $C(q_i)$ is the wholesale price for an order of size q_i and $\Pi_i(q_i)$ is the profit of manufacturer i given her production quantity q_i . Specifically, we can write **M1**'s and **M2**'s respective profits for different production quantities as follows:

$$\begin{aligned}
 q_i = 2: \Pi_1 &= (10.5 - 2 - 3 - 1.25) \times 2 = 8.5, \\
 \Pi_2 &= (10.5 - 2 - 3 - 0.5) \times 2 = 10, \\
 q_i = 4: \Pi_1 &= (10.5 - 4 - 2.25 - 1.25) \times 4 = 12, \\
 \Pi_2 &= (10.5 - 4 - 2.25 - 0.5) \times 4 = 15, \\
 q_i = 6: \Pi_1 &= (10.5 - 6 - 2 - 1.25) \times 6 = 7.5, \\
 \Pi_2 &= (10.5 - 6 - 2 - 0.5) \times 6 = 12.
 \end{aligned}$$

Each manufacturer will choose the quantity that maximizes her profit. Thus, both **M1** and **M2** produce 4 units, and earn profits of \$12 and \$15, respectively. As **M2** has a significant cost advantage over **M1**, she enjoys a higher profit than **M1** although both manufacturers produce the same amount. The supplier's profit is $C(q_1) \times q_1 + C(q_2) \times q_2 - 2 \times F = (2.25 \times 4 - 3.50) \times 2 = \11 .

Now, let us consider the case where the manufacturers engage in collaborative procurement. In this case, the two manufacturers order jointly, hence the unit cost is

determined by their total quantity (i.e., if both manufacturers produce 2 units, the unit cost is \$2.25 per unit; otherwise, it is \$2 per unit). We observe that both manufacturers continue to produce 4 units, but they now pay only \$2 per unit instead of \$2.25 per unit, thus they increase their profits to \$13 and \$16, respectively. Through collaborative procurement the manufacturers present a unified front to the supplier and subsequently increase their buying power. When the manufacturers collaborate, the supplier's profit is $C(q_1 + q_2) \times (q_1 + q_2) - F = \12.50 . Since the supplier has to process one large order rather than two smaller orders, he benefits from economies of scale. He may pass some of these benefits to buyers by lowering his prices [18].

The fact that the manufacturers benefit from collaboration when they serve two different markets is quite intuitive. However, even when the manufacturers *compete in the same market*, they may choose to collaborate and help decrease each other's costs. This is true even for a manufacturer who has a significant cost advantage over her competitor. To see why, suppose that the manufacturers choose their production quantities simultaneously and the market price is then set as a function of the total quantity as follows:

$$P = (10.5 - (q_1 + q_2))^+ \quad (2)$$

$$= \max\{0, 10.5 - (q_1 + q_2)\}, \quad (3)$$

where q_1 and q_2 are the respective production quantities of **M1** and **M2** and P is the market price. This game is Cournot competition (Cournot competition models a setting where competing companies choose their output quantities independently and simultaneously; with a slight twist: instead of charging a constant per unit price for the subcomponent, the supplier offers a discount to each manufacturer).

Using the techniques covered in the article titled *Nash Equilibrium (Pure and Mixed)* in this encyclopedia, we can find the unique Nash equilibrium of this game under the cases of competition and collaboration. The equilibrium quantities for **M1** and **M2** are 2 units and 4 units, respectively, under both cases. When the manufacturers

do not collaborate, their profits are \$0.50 and \$7, respectively. The supplier's profit is \$8. When the manufacturers collaborate, their profits are \$2.50 and \$8, respectively. That is, when they collaborate, both manufacturers are better off; namely, collaboration Pareto dominates competition. Note that the manufacturers' profits increase disproportionately: **M1**, who has a cost disadvantage, benefits from collaboration more than her competitor **M2** does. The supplier benefits from economies of scale as before, and increases his profits to \$8.50 when the manufacturers collaborate.

This simple example leads to several questions; for example, under what demand conditions would manufacturers prefer collaboration? When would a supplier be better off providing a discount scheme that enables collaboration among manufacturers? What about the impact of collaboration on social welfare? Such questions are the premise of several academic papers that we review next.

LITERATURE REVIEW ON HORIZONTAL COLLABORATION

Collaboration and Social Welfare

Mathewson and Winter [19] study a setting where a group of buyers collaborates to lower their costs and contracts with a group of suppliers. Such coalitions may be considered legally troublesome; they impose negative externality to buyers outside the coalition as these buyers face higher prices and lower availability. However, the authors conclude that coalitions leading to group purchasing may actually increase social welfare.

Value of Collaboration for Buyers

Keskinocak and Savaşaneril [20] study group purchasing among competing buyers with a single-supplier, multiple-buyers model. The supplier offers a quantity discount scheme to the buyers; that is, multiple-buyers can procure together to obtain lower prices by increasing their buying power. The authors show that when the buyers do not have capacity constraints (and are identical in terms of

costs), they always earn more profits by collaborating. Interestingly, the supplier also prefers to sell to collaborating buyers. However, when the buyers have limited capacity, collaboration may not always be preferable: a buyer is willing to collaborate if collaboration increases the quantity that he purchases.

Griffin *et al.* [21] study alternative buyer strategies in markets where procurement costs are affected by economies of scale in the suppliers' production costs and by economies of scope in transportation. They consider buyer strategies with different types of collaboration, namely, (i) no collaboration among buyers or buyer divisions, (ii) intra-enterprise collaboration among the purchasing organizations of the same buyer enabled by an internal intermediary, and (iii) inter-enterprise (full) collaboration among multiple-buyers enabled by a third party intermediary. They find that when the potential benefits from economies of scope are high, intra-enterprise collaboration performs very well. When the potential benefits from economies of scale are high, the authors observe that buyer strategies need to consider potential future trades in the market by other buyers while contracting with a supplier. Their computational analysis indicates that the potential benefits of collaboration are highest in capacitated markets with high fixed production and/or transportation costs.

Value of Collaboration for Suppliers

Like Keskinocak and Savaşaneril [20], Anand and Aron [22] study collaboration between multiple-buyers who purchase from a single-supplier. Different from Keskinocak and Savaşaneril, their model analyzes group purchasing under demand uncertainty. In Anand and Aron's model, the supplier posts a quantity discount scheme. Then, buyers arrive and demand single units. As the total number of units demanded increases, the price buyers pay drops. Eventually all buyers pay the same price for the product. The supplier does not know the demand function prior to setting the discount scheme. Anand and Aron's goal is to compare the performance of group buying to posted prices. They show that the supplier prefers

group buying to posted prices (i) as demand heterogeneity increases and (ii) if he can postpone the production decision until after demand is realized *and* if he enjoys scale economies in production.

Product Substitutability and Value of Collaboration

Using concepts from cooperative game theory (see the section titled “Cooperative Games” in this encyclopedia), Granot and Sošić[23] study collaboration in electronic marketplaces. The authors characterize the conditions under which a firm would prefer to collaborate with a model of three retailers whose products may have a certain degree of substitutability. They show that all three retailers collaborate either when all products are nonsubstitutable or when all three products are highly substitutable and the retailers benefit from collaboration equally.

CONCLUSIONS AND KEY MANAGERIAL INSIGHTS

The advantages of successful collaborative procurement are numerous, including lower costs, reduced inventory, increased sales, increased revenue, improved customer service, and more efficient use of resources. Despite its many advantages, collaboration does not come easily to companies. Establishing a successful collaboration requires *commitment* from all involved parties. Collaboration should start internally before extending to external partners. Companies should know *why* as well as *with whom* they want to collaborate. *Trust* is key for a true collaboration. Partners should be ready to *share* practices, processes, and information, even proprietary information, when necessary. Roles, responsibilities, expectations, and goals should be clearly documented. As is the case with any process improvement, setting short-term and long-term *performance measures* to evaluate the success of collaboration is essential. Furthermore, companies should be ready to redefine the scope of their relationships based on these performance measures and as their partnership evolves.

It is important that the academic literature continues to guide companies in their quests for collaboration. Understanding the role of collaboration in environments with uncertainty is important. Decision support tools and models for net landed cost would be especially beneficial. Collaboration requires truthfulness and trust. Conditions under which such truthfulness can be achieved, especially when companies have private information, should be characterized. Long-term and relational models to study collaborative procurement would be valuable.

COLUMN GENERATION

MARCO E. LÜBBECKE
Chair of Operations Research,
RWTH Aachen University,
Aachen, Germany

Column generation is a classical technique to solve a mathematical program by iteratively adding the variables of the model [1]. Typically, only a tiny fraction of the variables is needed to prove optimality, which makes the technique interesting for problems with a huge number of variables. The method is often said in one sentence with Dantzig–Wolfe decomposition [2] (see also **Dantzig–Wolfe Decomposition**), as it is particularly effective when the matrix has a special structure like bordered block-diagonal or staircase forms.

We wish to clarify one point right at the start. Even though the method was termed *generalized linear programming* in the early days, it never became competitive for solving linear programs, except for special cases [3]. In addition, tailored implementations were designed to exploit matrix structures, but they did not perform better than the simplex method [4]. In contrast, column generation is a real winner in the context of integer programming (see **Branch-Price-and-Cut Algorithms**). This made the powerful method a *must-have* in the computational mixed integer programming “bag of tricks.”

We assume that the reader is familiar with basic linear programming duality and the simplex method (see also the section titled “Fundamental Techniques” in this encyclopedia).

COLUMN GENERATION

We would like to solve a linear program, called the *master problem* (MP),

$$v(\text{MP}) := \min \sum_{j \in J} c_j \lambda_j$$

$$\text{subject to } \sum_{j \in J} \mathbf{a}_j \lambda_j \geq \mathbf{b} \quad (1)$$

$$\lambda_j \geq 0, \quad j \in J,$$

with $|J| = n$ variables and m constraints. In many applications, n is exponential in m and working with (1) explicitly is not an option because of its sheer size. Instead, consider the *restricted master problem* (RMP), which contains only a subset $J' \subseteq J$ of variables. An optimal solution λ^* to the RMP need not be optimal for the MP, of course. Denote an optimal dual solution to the RMP by π^* . In the *pricing step* of the simplex method (see also **The Simplex Method and Its Complexity**), we look for a nonbasic variable of negative reduced cost to enter the basis. To accomplish this in column generation, one solves the *pricing problem* (or *subproblem*) PP:

$$v(\text{PP}) := \min \{c_j - \pi^* \mathbf{a}_j \mid j \in J\}. \quad (2)$$

When $v(\text{PP}) < 0$, the variable λ_j and its coefficient column $(c_j, \mathbf{a}_j)$ corresponding to a minimizer j are added to the RMP; this is solved to optimality to obtain optimal dual variable values, and the process iterates until no further improving variable is found. In this case, λ^* optimally solves the MP (1) as well. In particular, column generation inherits finiteness and correctness from the simplex method, when cycling is taken care of.

It does not seem clear why Equation (2) should be of any help when $|J|$ is large. However, in almost every application, indices in J enumerate entities, which can well be described as the feasible domain X of an optimization problem

$$\min_{\mathbf{x} \in X} \{c(\mathbf{x}) - \pi^* a(\mathbf{x})\}, \quad (3)$$

where $c_j = c(\mathbf{x}_j)$ and $\mathbf{a}_j = a(\mathbf{x}_j)$, and $\mathbf{x}_j \in X$ corresponds one-to-one to $j \in J$. That is, instead of *explicitly* pricing all candidate variables, we solve a typically well-structured optimization problem, making the search for a variable of negative reduced cost *implicit*.

Technically, our notation suggests that X be finite, but this need not be the case.

Consider the one-dimensional cutting-stock problem, the classical example in column generation introduced in Gilmore and Gomory [5]. We are given paper rolls of width W , and m demands $b_i, i = 1, \dots, m$, for orders of width w_i . The goal is to minimize the number of rolls to be cut into orders, such that the demand is satisfied. A standard formulation is

$$\min \left\{ \mathbf{1}\lambda \mid A\lambda \geq \mathbf{b}, \lambda \in \mathbb{Z}_+^{|J|} \right\}, \quad (4)$$

where A encodes the set of $|J|$ feasible cutting patterns, that is, $a_{ij} \in \mathbb{Z}_+$ denotes how often order i is obtained when cutting a roll according to $j \in J$. From the definition of feasible patterns, the condition $\sum_{i=1}^m a_{ij}w_i \leq W$ must hold for every $j \in J$, and λ_j determines how often the cutting pattern $j \in J$ is used. The linear relaxation of Equation (4) is then solved via column generation, where the pricing problem is a *knapsack problem*.

Dual Bounds. During column generation we have access to a dual bound on $v(\text{MP})$ so that we can terminate the algorithm when a desired solution quality is reached. Let $v(\text{RMP})$ denote the optimum of the current RMP. When we know that $\sum_{j \in J} \lambda_j \leq \kappa$ for an optimal solution of the MP, we cannot improve $v(\text{RMP})$ by more than κ times the smallest reduced cost $v(\text{PP})$. Hence

$$v(\text{RMP}) + \kappa \cdot v(\text{PP}) \leq v(\text{MP}). \quad (5)$$

An important special case is $\kappa = 1$ when a *convexity constraint* is present; see the section titled “Dantzig–Wolfe Decomposition.” This bound is tight as $v(\text{PP}) = 0$ when column generation terminates. Note that $v(\text{PP})$ is not available when the pricing problem is solved heuristically. When the objective function is a sum of all variables, that is, $\mathbf{c} \equiv \mathbf{1}$, we use $\kappa = v(\text{MP})$ and obtain $v(\text{RMP})/(1 - v(\text{PP})) \leq v(\text{MP})$. There are other proposals, for example, such as that of Farley [6], and also tailored bounds for special problems, for example, such as that of Valério de Carvalho [7]. In general, the dual bound is not monotone over the iterations (*yo-yo effect*).

Dantzig–Wolfe Decomposition

The classical scenario of column generation is set in the context of Dantzig–Wolfe decomposition [2] in which a special structure of the typically very sparse coefficient matrix is exploited (see also **Dantzig–Wolfe Decomposition**). Consider a linear program, called the *original formulation* in this context:

$$\begin{aligned} \min \quad & \mathbf{c}\mathbf{x} \\ \text{subject to} \quad & A\mathbf{x} \geq \mathbf{b} \\ & D\mathbf{x} \geq \mathbf{d} \\ & \mathbf{x} \geq \mathbf{0}. \end{aligned} \quad (6)$$

Let $X = \{\mathbf{x} \in \mathbb{Q}_+^n \mid D\mathbf{x} \geq \mathbf{d}\}$. Using the representation theorems for convex polyhedra by Minkowski and Weyl [8], we can write each $\mathbf{x} \in X$ as a finite convex combination of extreme points $\{\mathbf{x}_p\}_{p \in P}$ plus finite nonnegative combination of extreme rays $\{\mathbf{x}_r\}_{r \in R}$ of X , that is,

$$\begin{aligned} \mathbf{x} &= \sum_{p \in P} \mathbf{x}_p \lambda_p + \sum_{r \in R} \mathbf{x}_r \lambda_r, \quad \sum_{p \in P} \lambda_p = 1, \\ \lambda &\in \mathbb{Q}_+^{|P|+|R|}. \end{aligned} \quad (7)$$

Substituting for $\mathbf{x}$ in Equation (6), thereby eliminating constraints $D\mathbf{x} \geq \mathbf{d}$, and letting $c_j = \mathbf{c}\mathbf{x}_j$ and $\mathbf{a}_j = A\mathbf{x}_j, j \in P \cup R$, we obtain an equivalent *extended formulation*:

$$\begin{aligned} \min \quad & \sum_{p \in P} c_p \lambda_p + \sum_{r \in R} c_r \lambda_r \\ \text{subject to} \quad & \sum_{p \in P} \mathbf{a}_p \lambda_p + \sum_{r \in R} \mathbf{a}_r \lambda_r \geq \mathbf{b} \\ & \sum_{p \in P} \lambda_p = 1 \\ & \lambda \geq \mathbf{0}, \end{aligned} \quad (8)$$

which is solved by column generation. Let π^*, π_0^* denote a dual-optimal solution to the RMP obtained from Equation (8), where variable π_0 corresponds to the *convexity constraint* $\sum_{p \in P} \lambda_p = 1$. The subproblem (3) is to check whether $\min_{j \in P \cup R} \{c_j - \pi^* \mathbf{a}_j - \pi_0^*\} < 0$. By our previous linear transformation, this results in solving the linear program

$$\min \{(\mathbf{c} - \pi^* A)\mathbf{x} - \pi_0^* \mid D\mathbf{x} \geq \mathbf{d}, \mathbf{x} \geq \mathbf{0}\}. \quad (9)$$

When the minimum is negative and finite, an optimal solution to Equation (9) is an extreme point $\mathbf{x}_p$ of X , and we add a variable with coefficient column $[\mathbf{c}\mathbf{x}_p, (A\mathbf{x}_p), 1]$ to the RMP. When the minimum is minus infinity, we obtain an extreme ray $\mathbf{x}_r$ of X as a homogeneous solution to Equation (9), and we add the column $[\mathbf{c}\mathbf{x}_r, (A\mathbf{x}_r), 0]$ to the RMP. It is particularly interesting that the MP stays a linear program even when the subproblem is nonlinear.

The usefulness of Dantzig–Wolfe decomposition becomes more apparent in the practically relevant case where D has a block-diagonal structure, that is,

$$D = \begin{pmatrix} D^1 & & \\ & D^2 & \\ & & \ddots \\ & & & D^K \end{pmatrix} \quad \mathbf{d} = \begin{pmatrix} \mathbf{d}^1 \\ \mathbf{d}^2 \\ \vdots \\ \mathbf{d}^K \end{pmatrix}. \quad (10)$$

Each $X^k = \{D^k \mathbf{x}^k \geq \mathbf{d}^k, \mathbf{x}^k \geq \mathbf{0}\}$, $k = 1, \dots, K$, gives rise to a representation as in Equation (7). The decomposition yields K subproblems, each with its own convexity constraint and associated dual variable π_0^k :

$$\min \left\{ (\mathbf{c}^k - \pi A^k) \mathbf{x}^k - \pi_0^k \mid \mathbf{x}^k \in X^k \right\}, \quad k = 1, \dots, K, \quad (11)$$

where $\mathbf{c}^k$ and A^k correspond to variables $\mathbf{x}^k$. An optimal solution to the RMP is found when no minimum in Equation (11) is negative. The dual bound (5) can be adapted.

There are other special matrix structures that can be exploited, for example, the so-called staircase form of matrices, which arises in multiperiod or multistage planning problems, in particular in stochastic programming. In the easiest case, the matrix of the pricing problem has bordered block-diagonal structure again, and the Dantzig–Wolfe decomposition can be iteratively applied (also known as *nested column generation*).

Lagrangian Relaxation

For a bordered block-diagonal matrix, in particular, Dantzig–Wolfe decomposition

can be interpreted as keeping complicating constraints in the MP while exploiting a particular structure in the subproblems. *Lagrangian relaxation* [9] proceeds the other way round: the complicating constraints $A\mathbf{x} \geq \mathbf{b}$ are relaxed and their violation is penalized in the objective function via multipliers $\pi \geq \mathbf{0}$ (see also **Lagrangian Optimization for LP**). This results in the *Lagrangian subproblem*

$$L(\pi) := \min_{\mathbf{x} \in X} \mathbf{c}\mathbf{x} - \pi(A\mathbf{x} - \mathbf{b}), \quad (12)$$

which gives a lower bound on the optimum in Equation (6) for any $\pi \geq \mathbf{0}$. We obtain the best such bound by solving the *Lagrangian dual problem*

$$\max_{\pi \geq \mathbf{0}} L(\pi). \quad (13)$$

The Lagrangian function $L(\pi)$ is piecewise linear, concave, and subdifferentiable (but not differentiable). Since they are very easy to implement, the most popular choice to obtain optimal or near-optimal multipliers are the subgradient algorithms (see also **Subgradient Optimization**). By duality, in the optimum $v(\text{RMP}) = \pi^* \mathbf{b}$, and Equation (12) can be written as

$$\begin{aligned} L(\pi) &= \pi^* \mathbf{b} + \min_{\mathbf{x} \in X} (\mathbf{c} - \pi A)\mathbf{x} \\ &= v(\text{RMP}) + v(\text{PP}), \end{aligned}$$

that is, the dual bound in Dantzig–Wolfe decomposition and the Lagrangian bound coincide (see also **Relationship Among Benders, Dantzig–Wolfe, and Lagrangian Optimization**).

Row and Column Generation

Linear programs may have not only a large number of variables but also (too) many rows, for example, when constraints are formulated on all subsets of a given ground set (like sub-tour elimination constraints for the TSP). In such cases, one iteratively adds only those constraints that are violated by the current solution. The identification of a violated constraint (or the detection that none exists) is called *separation*. Embedded in a branch-and-bound algorithm, *cutting-plane methods*

became instrumental (and thus the standard) in solving mixed *integer* programs. Now, row and column generation obviously cannot be viewed independently. Even though some general ideas exist on how the pricing problem needs to be modified in order to cope with the dual variables from the additional rows, such approaches are still mainly problem specific (see also **Branch-Price-and-Cut Algorithms**).

Mixed Integer Programs

When solving a mixed integer program by branch-and-bound, the (linear) relaxation serves the purpose of providing a dual bound on the optimal objective function value. When the relaxation is solved by column generation in each node, one is referring to branch-and-price (see also **Branch-Price-and-Cut Algorithms**). We cannot overstate the fact that the primary use of column generation is in this context, and it is becoming increasingly popular as column generation reformulations often give much stronger bounds than the original LP relaxation. Many people actually refer to solving an integer program when they speak of column generation.

The Dantzig–Wolfe decomposition principle can be generalized to mixed integer programs in several ways. However, the basic column generation procedure to solve the linear relaxation remains the same. One drawback, the slow convergence (see the section titled “Stabilization of Dual Variables”), may even become less severe. When a dual bound LB is available, and the objective function coefficients are all integers, that is, $c_j \in \mathbb{Z}$, $j \in J$, column generation can be stopped as soon as $\lceil LB \rceil = \lceil z \rceil$. When one is aiming for quick integer solutions one may even terminate the process prematurely, and take a branching decision as soon as column generation starts tailing off. In this case the node’s dual bound is not valid, so it is set to that of the father node, and this *early termination* even is exact in principle.

ALGORITHMIC ISSUES

The dual of the RMP is the dual of the MP with rows omitted, and hence a relaxation.

Therefore, the pricing problem is a *separation problem* for the dual; column generation is a cutting plane method to solve the Lagrangian dual (13). This explains why many researchers relate it to the Kelley [10] and Cheney-Goldstein [11] cutting plane methods that are known for maximizing a concave continuous function. The dual point of view (see Briant *et al.* [12] for a more detailed discussion) revealed central algorithmic issues in column generation. In particular, one should re-read this section after having read the section titled “Stabilization of Dual Variables” on dual variable stabilization.

Note that there is a theoretical consequence from the equivalence of separation and optimization [13]. Even exponential size RMPs (linear programs) are solvable in polynomial time (in theory by the Ellipsoid method) when the pricing problem is solvable.

Master Problem: Computing Primal and Dual Solutions

The purpose of the RMP is to provide dual variable values: To communicate to the pricing problem which primal variables are needed to come closer to dual feasibility, and thus primal optimality. Note that we never need a primal feasible solution before optimality is reached, not even to calculate dual bounds. That is, the RMP serves the same purpose as, for example, subgradient methods in Lagrangian relaxation, and this connection can be exploited.

Initialization, Infeasibility, and Farkas Pricing. Even when the MP has a feasible solution, there are two important situations when the RMP is not feasible: in the beginning when no variables have been generated yet, and after branching when solving an integer program. In the traditional “phase I” approach [14] artificial variables with a “big M ” penalty cost are introduced. A smaller M gives a tighter upper bound on the respective dual variables, and may reduce the *heading-in effect* [15] of initially producing irrelevant columns. Heuristic estimates of the optimal dual variable values can be used for this purpose [16]. Furthermore, one may warm-start

from a previous similar run [17] or use a primal heuristic to produce an initial solution.

Column generation provides another way for turning an infeasible RMP feasible via the well-known fact that the dual of an infeasible linear program is unbounded (if not infeasible). This is formalized in Farkas' Lemma, which states that either $A\mathbf{x} = \mathbf{b}$, $\mathbf{x} \geq \mathbf{0}$ is feasible or there is a vector $\boldsymbol{\pi}$ with $\boldsymbol{\pi}A \leq \mathbf{0}$ and $\boldsymbol{\pi}\mathbf{b} > 0$. Such a vector $\boldsymbol{\pi}$, which is interpreted as a ray in the dual, *proves* the infeasibility of the first system as the condition $\boldsymbol{\pi}A\mathbf{x} = \boldsymbol{\pi}\mathbf{b}$ cannot be fulfilled. The idea is now to add a variable to A with coefficient column $\mathbf{a}$ with $\boldsymbol{\pi}\mathbf{a} > 0$, which thus *destroys* this proof of infeasibility. Such a variable can be found (or concluded that none exists) by solving

$$\max_{\mathbf{x} \in X} \{\boldsymbol{\pi}^* \mathbf{a}(\mathbf{x})\} = \min_{\mathbf{x} \in X} \{-\boldsymbol{\pi}^* \mathbf{a}(\mathbf{x})\}, \quad (14)$$

which is nothing else but the standard pricing problem (3) with cost coefficients $c(\mathbf{x}) = 0$. The dual ray $\boldsymbol{\pi}^*$ is typically provided by the LP solver in the case of an infeasible linear program. While this method appears to belong to the *folklore*, the name *Farkas pricing* has been introduced only recently in Achterberg [18] within the SCIP framework (see section titled "Acceleration Techniques and Implementation Issues").

Algorithms: Pivots, Subgradients, Bundles, and Volumes. As for any linear program, it is not *a priori* clear which method of solving the RMP will perform "best." This may depend on the problem and the available solvers. Traditionally, primal or dual simplex methods are used (see Lasdon [19] for general comments on their suitability), but there are many alternatives. The *sifting method* [20], which is some sort of static column generation, can be a reasonable complement for large-scale RMPs [17,21]. Interior point methods like the *barrier method* can prove effective, although there is no warm-start (yet). Also, the *analytic center cutting plane method* [22] is advantageous as it produces interior point dual solutions. In addition to these general-purpose methods, one may stronger exploit duality.

As we have stressed before, the RMP should furnish dual multipliers. After some

initial iterations, a simplex method may produce relevant dual solutions which lead to progress, but then switching to a subgradient or more elaborate method to improve the dual solution may produce better dual bounds, and thus faster termination [23–25]. This can be cheaper and more stable (see the section titled "Stabilization of Dual Variables"), and may considerably reduce computation times. As the literature on Lagrangian relaxation is rich, there are many proposals for multiplier adjustment in subgradient methods that can be adapted to the column generation context. The RMP may itself be solved by subgradient algorithms by relaxing all its constraints in the objective function. This can be used as a primal heuristic as well, as proposed for set covering applications [26–28].

Subgradient algorithms suffer from a very restricted information; only the current subgradient is available. *Bundle methods* [29,30] therefore work with a set of subgradients, the *bundle*, from which the name is derived. It is true that a simplex method maintains a kind of bundle as well (the variables in the basis) but bundle methods may be more flexible. Bundle methods apply the proximal point idea of (quadratically) penalizing a deviation of the next iterate from the current best one in terms of the dual bound. This makes them attractive in the context of the section titled "Stabilization of Dual Variables" and explains their use in column generation [31]. It usually takes only a few iterations to produce an approximately optimal primal–dual pair.

The *volume algorithm* [32] is another extension of subgradient algorithms that also rapidly produces good approximations. It is so named because of a new way of looking at linear programming duality: using volumes below the active faces to compute the dual variable values and the direction of movement. The pricing subproblem is called with a dual solution "in a neighborhood" of an optimal dual solution. One can compute the probability that a particular column (which induces a face of the dual polyhedron) is generated. A modified subgradient method furnishes estimates of these probabilities, that is, approximate primal solutions. Primal feasibility may be mildly violated.

The volume algorithm, when used in alternation with the simplex method, produces dual solutions with a large number of nonzero variables [17], which may accelerate column generation. The computational experience has been promising [23,33] for various combinatorial optimization problems. Advantages of the volume algorithm are straight forward implementation with small memory requirements, numerical stability, and fast convergence.

Row Aggregation for Set Partitioning Problems. Primal degeneracy is an efficiency issue also in column generation, for example, for large-scale set partitioning problems. Because of the degenerate pivots, dual variables yield less reliable information for the pricing problem. A possible remedy is to group *similar* constraints and aggregate them into one [34], thus working with an RMP with much less rows. The intuition is that in applications like vehicle routing and crew scheduling, some activity sequences are more likely to occur than others: In airline crew scheduling a pilot usually stays on the same aircraft for several flight legs. Since aircraft itineraries are known prior to solving the crew pairing problem, it is natural to “guess” some aggregation of the flights to cover.

The method is not particular to column generation but can be used in this context. Most importantly, an aggregated RMP gives aggregated dual variables that need to be disaggregated. This should (and can) be done carefully so that the disaggregated dual solution fulfills many of the dual constraints. To ensure proper convergence and optimality, the aggregation is dynamically updated throughout the solution process. Tests conducted on the linear relaxation of the simultaneous vehicle and bus driver scheduling problem in urban mass transit show that this solution approach significantly reduces the size of the MP, the degeneracy, and the solution times, especially for larger problems: for an instance with 1600 set partitioning constraints, the RMP solution time is reduced by a factor of 8. A partial pricing strategy, called *multiphase dynamic constraint aggregation* [35], gives further significant speedup.

The Pricing Problem

The pricing problem provides a column that prices out profitably or proves that none exists. Any variable with negative reduced cost will do, be it obtained by an exact, approximate, or heuristic algorithm (the latter are first choice in terms of speed). One may even add positive reduced cost variables (possibly to a pool first). Sometimes relaxations of the pricing problem are solved, at the expense of a weaker dual bound, such as for vehicle routing problems [36]. Highly complex pricing problems (like in staff and duty scheduling) may be better solved by constraint programming as this offers a strong expressiveness of the model [37].

Pricing Schemes and Pricing Rules. For the simplex method many proposals have been made as to which columns to consider and according to which rule to choose when selecting a variable to enter the basis. Schemes like *full*, *partial*, or *cyclic* pricing find their analogs in column generation pricing. When there are *many* subproblems, it may be sensible to use partial/cyclic pricing in order to avoid the generation of many similar columns [38], but the number of iterations may increase. Dantzig’s classical most-negative reduced cost pricing rule is not the only choice. The Devex rule [39] (a practical variant of *steepest-edge* [40,41]) is reported to perform particularly well for set partitioning RMPs [42]. The dual analog, the *deepest-cut* rule [43], tries to cut away as much of the dual space as possible. It can be implemented heuristically and is reported to offer some speedup [44].

While steepest-edge is inherently based on the simplex method, deepest-cut is more independent from a particular solution method. This leads to the *lambda pricing* rule [20]. Assume that $c_j \geq 0, j \in J$. Clearly, the reduced cost $c_j - \pi^* \mathbf{a}_j$ is nonnegative for all $j \in J$ iff

$$\min_{j \in J} \left\{ \frac{c_j}{\pi^* \mathbf{a}_j} \mid \pi^* \mathbf{a}_j > 0 \right\} \geq 1. \quad (15)$$

At first glance, this is just a reformulation. However, Equation (15) takes advantage of

structural properties of (particular) set partitioning problems: picking columns with a small ratio accounts for smaller cost coefficients as well as for more nonzero entries in $\mathbf{a}_j$.

It is common in cutting plane algorithms to fill a *cut pool* first and select a *good* subset of cuts from it according to criteria like efficiency, orthogonality, sparsity, and others [18]. It remains to be seen how such criteria can be defined and applied for selecting good columns. Attempts to characterize dual facets [42] do not appear to have had any practical impact so far. It would be interesting to see other pricing rules *particular* to column generation, for example, with the aim of stabilization.

Pricing Problems when Solving Integer Programs. When the subproblem's domain X in Equation (3) is a mixed integer set, for example, when a Dantzig–Wolfe type decomposition is applied to a mixed integer original problem (6), pricing problems become mixed integer programs themselves (see also **Branch-Price-and-Cut Algorithms**). It is well known [9] that the dual bound from the RMP can be stronger than the LP relaxation only when the subproblem does not possess the *integrality property*. That is, the linear relaxation of the pricing problem should not give an integer solution. The trade-off in choosing a decomposition is between a strong dual bound (by adding also complicating constraints to the subproblem) and the manageability of the subproblem (by avoiding this). Sometimes a combinatorial algorithm is available for the pricing problem and a faster alternative to an integer program; often this is a dynamic program (like for resource constrained shortest path problems in routing applications), which has the advantage of providing more than one solution to the pricing problem. The latter can be achieved with integer programs as well as by using the *solution pool* that state-of-the-art solvers offer.

In particular, with the help of pricing heuristics, one often generates columns that resemble a good *integer* solution rather than an optimal *fractional* one (which may be much harder to characterize). One should keep in mind that what helps the integer

program need not help the linear program. Still, for example, for set partitioning RMPs a reasonable strategy is to generate columns of a rich diversity [45] (*complementary columns*).

STABILIZATION OF DUAL VARIABLES

Column generation is known to suffer from *tailing off* [46], that is, there is only incremental progress per iteration as we get closer to the optimum, in particular, for large and degenerate problems. There are several partial explanations (see Desrosiers and Lübbecke [47] for a summary), but the main reason lies in the *unstable* behavior of the dual variables. A dual solution may be far apart from the previous one (*bang-bang effect*, in Briant *et al.* [12] an example provided by Nemirovskii is cited, which drastically shows this behavior). *Stabilization* of the dual variables tries to reduce this effect. The principles are well established in the nonlinear programming world; choosing *good separation points* in cutting plane algorithms is the analogous concept [48].

It should be noted that in the case that stabilization is successful, regardless of the method employed, one typically observes a reduction in the number of column generation iterations. The downside of it is that the pricing problems become harder to solve on an average. However, among more sophisticated implementation techniques, stabilization may provide the largest performance gains [15].

Interior Point Stabilization

Solving the RMP by a simplex method gives an extreme point of the optimal face of the dual polyhedron. When this face has a large dimension, for example, when the primal is highly degenerate, there may be many extreme points, and the one obtained is essentially a “random choice” [20]. This extreme point is cut off in the next iteration; however, one would rather like to cut off the whole optimal face. In that sense, a simplex method may yield a “bad representative” of the optimal face. An immediate remedy to this may be to use an interior point

method instead, as one would cut off an interior point of the optimal face. Particular proposals have been using *analytic centers* [49], *volumetric centers*, and *central paths* [50], among others. Such concepts have been discussed for cutting plane algorithms as well [48].

A simplex-method-based approach to obtain a solution in the interior of the dual-optimal face is taken in Rousseau *et al.* [51]. It works in two steps and exploits the extremity of basic solutions. First, the RMP is solved and the objective function value is fixed to the optimum by adding an additional constraint. Then, several random objective functions $\mathbf{c}$ are chosen (and also the opposite direction $-\mathbf{c}$), each of which produces an extreme point of the optimal face. The final dual solution is a convex combination of all extreme points obtained. This approach is computationally expensive but easy to implement.

Boxstep Method

Instead of producing rather arbitrary interior points, one may introduce a control of the dual solution's trajectory. By imposing lower and upper bounds, dual variables are constrained to lie "in a box around" the previous dual solution π^* . The RMP that is thus restricted is reoptimized. If the new dual optimum is attained on the boundary of the box, we have a direction toward which the box should be relocated. Otherwise, the optimum is attained in the box's interior, producing the sought global optimum. This is the principle of the *Boxstep* method [52,53] and the basic idea of using a *stability center*, that is, our current best guess of an optimal dual solution that is in some sense "more reliable" than the other dual solutions. This is well known, for example, in trust-region methods, and it is the underlying mechanism of in what follows.

Polyhedral Penalty Terms

A hard-coded box is not very flexible. Instead, *stabilized column generation* [54] automates the recentering of the box to the current dual solution. Consider the following linear

program:

$$\begin{aligned} \min \quad & \mathbf{c}\lambda - \delta_- \mathbf{y}_- + \delta_+ \mathbf{y}_+ \\ \text{subject to} \quad & A\lambda - \mathbf{y}_- + \mathbf{y}_+ = \mathbf{b} \\ & \mathbf{y}_- \leq \boldsymbol{\varepsilon}_- \\ & \mathbf{y}_+ \leq \boldsymbol{\varepsilon}_+ \\ & \lambda, \mathbf{y}_-, \mathbf{y}_+ \geq \mathbf{0} \end{aligned} \quad (16)$$

and its dual:

$$\begin{aligned} \max \quad & \pi \mathbf{b} - \boldsymbol{\varepsilon}_- \mathbf{w}_- - \boldsymbol{\varepsilon}_+ \mathbf{w}_+ \\ \text{subject to} \quad & \pi A \leq \mathbf{c} \\ & -\pi - \mathbf{w}_- \leq -\delta_- \\ & \pi - \mathbf{w}_+ \leq \delta_+ \\ & \mathbf{w}_-, \mathbf{w}_+ \geq \mathbf{0}. \end{aligned} \quad (17)$$

Surplus and slack variables $\mathbf{y}_-$ and $\mathbf{y}_+$, respectively, perturb $\mathbf{b}$ by $\boldsymbol{\varepsilon} \in [-\boldsymbol{\varepsilon}_-, \boldsymbol{\varepsilon}_+]$, which helps to reduce degeneracy. The interpretation of Equation (17) is more interesting. The dual variables π are restricted to the interval $[\delta_- - \mathbf{w}_-, \delta_+ + \mathbf{w}_+]$ that is, deviation of π from the soft interval $[\delta_-, \delta_+]$ is allowed but penalized by an amount of $\boldsymbol{\varepsilon}_-, \boldsymbol{\varepsilon}_+$ per unit, respectively. From Equation (16) we obtain an optimal solution to the unperturbed problem $\min\{\mathbf{c}\lambda \mid A\lambda = \mathbf{b}, \lambda \geq \mathbf{0}\}$ when $\boldsymbol{\varepsilon}_- = \boldsymbol{\varepsilon}_+ = \mathbf{0}$ or $\delta_- < \hat{\pi} < \delta_+$, where $\hat{\pi}$ is an optimal solution to Equation (17). Therefore, the stopping criteria of a column generation algorithm become $v(PP) = 0$ and $\mathbf{y}_- = \mathbf{y}_+ = \mathbf{0}$.

This approach may need some parameter tuning, but it offers considerably speedup for some problems [54]. The change in the RMP requires addition of upper bounded artificial variables only, which does not increase the size of the basis. It can be easily generalized to piecewise linear penalty functions with more pieces, where five pieces appear to give a good compromise [55], with a stronger penalty further away from the stability center. Note that Equation (16) is a relaxation of the unperturbed RMP, and it may be computed faster.

Bundle Methods: Quadratic Penalty Term

The aim of the penalty terms is to encourage a dual solution to stay close to the stability center; so the penalty is larger the further

away we go. Pictorially, a quadratic penalty function can achieve this goal better than a piecewise linear penalty, and *bundle methods* do precisely this: penalizing the Euclidean distance to the stability center. There is an extensive comparison between bundle methods and “classical” stabilization techniques in Briant *et al.* [12], and the current conclusion is that there is no clear winner. The situation may change in favor of bundle methods when future developments bring improvements, for example, in quadratic programming.

Convex Combinations with Previous Dual Solutions

A different approach to avoid (too) large steps in the dual space does not need any modification to the RMP at all, but convex combines the current dual solution π^* with a previous one $\hat{\pi}$, that is, the pricing problem is called with $\alpha\hat{\pi} + (1 - \alpha)\pi^*$ for $0 \leq \alpha \leq 1$. When a column is found it is added to the RMP only when it has negative reduced cost with respect to π^* . The dual bound is updated whenever $L(\alpha\hat{\pi} + (1 - \alpha)\pi^*) > L(\hat{\pi})$. An interesting property is that even in the case when no column was added to the RMP (a *mis-price*) it holds that the dual bound improves to at least $L(\hat{\pi}) + \alpha(v(\text{RMP}) - L(\hat{\pi}))$ [56]. As a consequence the duality gap $v(\text{RMP}) - L(\hat{\pi})$ is reduced at least by a factor $(1 - \alpha)^{-1}$, that is, the method not only converges but does so at a proven rate. Only a single parameter has to be calibrated; however, because of this static choice of α , the stability center moves with less flexibility than in the previous proposals.

The convex combination with a dual solution that produced the current best dual bound is a rediscovery of the *weighted Dantzig–Wolfe decomposition* method [57], in which α is updated in each iteration. The stability center $\hat{\pi}$ becomes more reliable (larger α) the more often it leads to an improvement of the dual bound.

Valid Inequalities in the Dual Space

A complementary stabilization technique is to add valid inequalities to the dual. A simple

proposal is the relaxation of RMP equalities to inequalities (when possible), which imposes sign constraints to the dual variables [5]. The concept of *dual-optimal inequalities* [58,59] is more refined. One adds constraints $\pi E \leq \mathbf{e}$, which are valid for the optimal face of the dual polyhedron. The consequence in the primal is that additional variables are introduced, and the RMP becomes $\min\{\mathbf{c}\lambda + \mathbf{e}\mathbf{y} \mid A\lambda + E\mathbf{y} \geq \mathbf{b}, \lambda, \mathbf{y} \geq \mathbf{0}\}$. Deep dual-optimal inequalities [59] may even cut away dual-optimal solutions except at least one.

As an example, consider the one-dimensional cutting stock problem (4). It can be easily shown that if the orders are ranked such that $w_1 < w_2 < \dots < w_m$, then the dual variables satisfy the *ranking constraints* $\pi_1 \leq \pi_2 \leq \dots \leq \pi_m$. These $m - 1$ dual constraints can be generalized to larger sets [58,59]. Let $S_i = \{s \mid w_s < w_i\}$. Then

$$\sum_{s \in S} w_s \leq w_i \Rightarrow \sum_{s \in S} \pi_s \leq \pi_i, \quad S \subset S_i, \quad (18)$$

which significantly reduces the number of iterations in difficult instances [59].

As dual inequalities relax the primal RMP, one has to ensure primal feasibility of the final λ^* , which can be done by slightly perturbing the RMP [59]. The usefulness of adding valid dual inequalities has been demonstrated by constraining the dual variables to a small interval around their optimal values [55,59] (or a heuristic good guess). Such *perfect dual information* is available, for example, for the cutting stock triplet-problems, where each roll is cut into exactly 3 orders without any wastage, where $\pi_i = w_i/W$, $i = 1, \dots, m$ is dual optimal. It is further known that restricting the dual space can reduce primal degeneracy [58].

ACCELERATION TECHNIQUES AND IMPLEMENTATION ISSUES

Column generation is easily understood in theory but an implementation may suddenly reveal that there are many small pieces that need to fit together. We mention some of these in the sequel.

Libraries, Frameworks, Modeling Languages

Most people who implement a column generation code will at least rely on some package that provides an efficient simplex algorithm. There are plenty of packages available, both commercial and open-source, such as CLP [60], GLPK [61], and Soplex [62]. As noted above, there are alternatives (at least complements) to the simplex method, like the bundle method [63]. When we implement only column generation, the main loop is quickly written. The major implementation effort then probably remains for the pricing problem. The situation is a little different when doing branch-and-price, but there are several frameworks that support its implementation (and thus in particular column generation) such as ABACUS [64], BCP [65], SCIP [18], and SYMPHONY [66].

Frameworks have the advantage that they may automatically take care of features like using a *column pool*, which contains variables from previous pricing rounds, or *lazy constraints*, which are separated only when needed. This can be useful for constraints that are unlikely to be tight at optimality [67]. The main benefit from a framework is that it manages the branch-and-price tree, and that standard branching schemes, and others are available.

It is a little less known fact that column generation can also be implemented within several modeling languages like GAMS [68] or OPL [69], but a true branch-and-price is usually not supported. Since the user does not have access to all the internals, this option is probably not quite suitable for exactly solving very difficult problems, but it can be useful for practitioners working with the modeling language.

Suboptimal Solutions

Column generation and branch-and-price are exact methods, that is, in theory we obtain an optimal solution. The crux is that in practice, this may happen after a too long computation time, and one may wish to resort to a suboptimal solution. Fortunately, the dual bound gives a guarantee on its quality at any time. Heuristics should be used to construct or improve primal and dual solutions

as often as it seems useful. This point cannot be overestimated.

Numerical computations on a computer are in limited precision and there are several tolerances to be thought of: What is negative reduced cost? When comparing against 0.0, one easily ends up in an infinite loop because of numerical inaccuracies. When does the primal bound match the dual bound closely enough? When an explicit perturbation of the right-hand sides is used, of what magnitude will it be? Typically, for each of these tolerances one chooses some small value in the order of 10^{-3} to 10^{-6} . One can access the topic a bit more rigorously using the notion of ε -optimality [12]. An alternative is to resort to exact (rational) arithmetic; but due to performance reasons this is only advisable for mission-critical linear and integer programs.

Practitioners interested in primal solutions (found quickly) may choose some sort of price-and-branch, that is, pregenerate a reasonable set of variables in several rounds, and then solve the resulting program with standard branch-and-bound.

Some Simple Ideas that Often Work

Again, think of heuristics everywhere. Preprocess your problem well, in particular, when solving integer programs. For many problems on networks, the graph can be significantly reduced. Use a profiler to identify which part of the algorithm is the bottleneck. Typically, this will be the pricing problem but sometimes reoptimizing the RMP can be extremely time-consuming as well. Try solving the RMP only approximately and improve the dual solution with some iterations with a method from the Lagrangian world. Try dual variable stabilization; see the section titled “Stabilization of Dual Variables.” Try to avoid solving the pricing problem to optimality too often. Again, use heuristics first, maybe even a cascade of heuristics of increasing complexity. Relaxations serve the same purpose. Experiment with different parameters, in particular, how many columns are added to the RMP in each iteration; too few do not yield enough progress, and too many slow down computations (a combinatorial algorithm, or the

solution pool of your solver can return more than one column). For large-scale problems, it pays to remove columns that are nonbasic for too many iterations.

Many acceleration techniques are problem-dependent, but can often be adapted. The survey [70] in the context of vehicle routing and crew scheduling is very helpful in this respect. Re-read about the algorithmic alternatives in the section titled “Algorithmic Issues,” all of which can be (and have been) modified and combined (see also the section titled “Nonsimplex Algorithms for LP” in this encyclopedia). When everything fails, you need to research your problem (more thoroughly)! A proof that an optimal primal (or dual) solution you are looking for has a particular structure may restrict the search a lot.

CONCLUSIONS

Despite the obvious similarity to cutting plane techniques—both methods dynamically extend the model—column generation has significant differences. While cutting planes *can optionally be* added to the (already optimally solved) linear relaxation in order to strengthen it, one *has to* add negative reduced cost variables for, otherwise, one does not obtain a valid dual bound. This makes the competition a bit unfair but we believe that the future lies in integrating the two methods into one anyway.

Even though column generation was inceptioned more than half a century ago, the last decade was the most active in research and implementation. The availability of powerful computers and electronic large-scale data of hard practical problems challenged the community. The influence of nondifferential convex analysis, in particular, the idea of dual variable stabilization, was beneficial for the field. Still, column generation and branch-and-price are not available as generic implementations, and we are eager to see this change.

Until this happens, there are very elaborate suggestions for tailoring the method to particular problems, sometimes even particular problem instances. While this is

questionable in terms of general-purpose applicability, it is the driving force for pushing the border. Many interesting developments will certainly follow.

Column generation is clearly a success story in large-scale *integer* programming. The dual bound obtained from an extended reformulation is often stronger, the tailing off effect can be lessened, and the knowledge of the original formulation provides us with a guide for branching and cutting decisions in the search tree. Today we are in a position where branch-and-price codes solve many large-scale problems of “industrial difficulty,” that no standard commercial solver could cope with.

FURTHER READING

Previous general reviews on column generation include Barnhart *et al.* [71], Desrosiers *et al.* [72], Soumis [73], and Wilhelm [74]. This article is based on Desrosiers and Lübbecke [47]. The literature on applications of branch-and-price and column generation grew so quickly in recent years (see the book by Desaulniers *et al.* [75]) that it is likely that someone already proposed at least a partial solution to the application you have in mind. For further reading on branch-and-price refer to Desrosiers and Lübbecke [76] and the article titled ***Branch-Price-and-Cut Algorithms***.

COMBINATORIAL AUCTIONS: COMPLEXITY AND ALGORITHMS

MARTIN BICHLER
Department of Informatics,
Technische Universität
München, Munich, Germany

An auction can be defined as “a market institution with an explicit set of rules determining resource allocation and prices on the basis of bids from the market participants” [1]. The competitive process serves to aggregate the scattered information about bidders’ valuations and to dynamically set a price. The auction format determines the rules governing when and how a deal is closed [2]. Auctions are typically evaluated using two main criteria, (*allocative*) *efficiency* and *revenue*. The former measures whether the objects end up with those bidders who value them most, while the latter focuses on the expected selling price.

Multiple object auctions can be divided into those, where *multiple units* of a single item are sold or where *multiple items* are sold. Of course, other combinations are also possible, where large quantities (multiple units) of different items get sold or bought, such as large quantities of different types of hard disk drives. Combinatorial auctions are a means to buy or sell multiple items. They have found application in a variety of domains such as the auctioning of spectrum licenses [3], truck load transportation [4], bus routes [5], and industrial procurement [6]. Original designs have been proposed by Rassenti *et al.* [7] for the allocation of airport time slots.

Combinatorial auctions address fundamental questions regarding efficiency and prices in markets [8,9]. These questions have been at the core of algorithmic mechanism design, a discipline at the intersection of Computer Science, Economics, and Operations Research. In this article, we focus on the design of combinatorial auctions, and also address some related types of auctions such as volume discount and multiattribute

auctions. We mainly look at the efficiency of auction formats as objective, as most of the literature in this area does. The article provides a concise introduction and is in parts based on publications such as Cramton *et al.* [10], which we refer to for a more detailed discussion. We assume that the reader has a basic knowledge about single-object auctions and the respective theory.

COMPLEXITY IN COMBINATORIAL AUCTIONS

Combinatorial auctions have been discussed in the literature, as they allow selling or buying a set of heterogeneous items to or from multiple bidders. Bidders can specify bundle bids, that is, a price is defined for a subset of the items for auction [10]. The price is only valid for the entire set and the set is indivisible. For example, in a combinatorial auction a bidder might want to buy 10 units of item x and 20 units of item y for a bundle price of \$100, which might be more than the total of the prices for the items x and y sold individually. We will refer to a bidding language as a set of allowable bid types (e.g., bundle bids or bids on price and quantity) in an auction. A bidding language allowing for bundle bids is also useful in procurement markets with economies of scope, where suppliers have cost complementarities due to reduced production or transportation costs for a set of items. In this case, we will discuss either about a combinatorial procurement auction or a combinatorial reverse auction.

Combinatorial auctions have been intensively discussed for the sale of spectrum licenses by the US Federal Communications Commission (FCC) [11]. The FCC divides licenses into different regions. Bidders - usually large telecom companies - often have superadditive preferences for licenses that are adjacent to each other. This can have advantages in advertising a service to the end customer, and also in the infrastructure that needs to be set up. In simultaneous

auctions where no bundle bids are allowed, bidders incur the risk that they only win a subset of items from a set of items that they are interested in, and that they end up paying too much for the subset. This is also called the *exposure problem*. These types of preferences can easily be considered in combinatorial auctions. However, the design of combinatorial auctions is such that several types of complexity can arise:

- The auctioneer faces *computational complexity* when determining an optimal allocation. The winner determination problem (WDP) in combinatorial auctions is an NP-hard problem [12]. In addition, the auctioneer needs to derive ask prices in iterative auctions, which is typically a hard computational problem as well.
- A bidder needs to determine his valuations for $2^m - 1$ bundles, where m is the number of items. We will refer to this as *valuation complexity*. Without restrictions, this would require to elicit 1023 valuations for an auction with only 10 items of interest.
- Even if the bidders knew their valuations perfectly, they would still need to decide how to respond during the auction. The issues relate to when and how they reveal their preferences. We will describe this as *strategic complexity*. Researchers have proposed different auction formats that exhibit various degrees of strategic complexity for bidders [13].
- Finally, *communication complexity* describes the number of messages that need to be exchanged between the auctioneer and the bidders in order to determine the optimal allocation. It has been shown that the communication complexity in combinatorial auctions is exponential in the number of items [14].

We focus on “Computational Complexity” in the next section and “Strategic Complexity” in the following section of this article. In the section titled “Combinatorial Auction Formats”, we discuss different auction

formats that have been suggested in the literature, and how they address these complexities.

COMPUTATIONAL COMPLEXITY

First, we will concentrate on the winner determination problem in combinatorial auctions [15–18]. It is a good example of the types of optimization problems that one encounters in various multiobject auctions. The following example with four bids and three items illustrates a simple procurement application (see Table 1). The buying organization needs different quantities of grain in different production sites. In this case, the buyer aggregates demand for multiple production sites, as suppliers might be able to provide better prices due to reduced production and transportation costs. Suppliers bid on subsets of the locations and each subset has a bundle price. In this article, we assume suppliers to provide the entire quantity for an item or location. In case they can provide subsets of the quantity, for example, only 500t of grain for Berlin, this is referred to as a multiunit combinatorial auction.

Given the bidder valuations for all possible bundles, the efficient allocation can be found by solving WDP. Let $\mathcal{K} = \{1, \dots, m\}$ denote the set of items indexed by k and $\mathcal{I} = \{1, \dots, n\}$ denote the set of bidders indexed by i with private valuations $v_i(S) \geq 0$ for bundles $S \subseteq \mathcal{K}$, and p as the price. This means, each bidder i has a valuation function $v_i : 2^{\mathcal{K}} \rightarrow \mathbb{R}_0^+$ that attaches a value $v_i(S)$ to any bundle

Table 1. Example with Bundle Bids

Line	Bids	Bids			
		B1	B2	B3	B4
1	1000t grain in Berlin	1	0	1	1
2	800t grain in Munich	0	1	1	1
3	800t grain in Vienna	1	1	1	0
4	Bid price (in thousands)	\$150	\$125	\$300	\$125

$S \subseteq \mathcal{K}$. In addition, we assume bidder values $v_i(S)$ to be independent and private (i.e., only known to the bidder), the bidders' utility function to be quasi-linear (i.e., the payoff of a bidder $\pi_i(S) = v_i(S) - p$) with free disposal (i.e., if $S \subset T$ then $v_i(S) \leq v_i(T)$). There are other situations where valuations are interdependent, such as the sale of a tract of land with an unknown amount of oil underground, where the bidders may have different estimates of the amount of oil based on privately conducted tests, but the final value is the same for all bidders. We focus on independent and private valuations in this article.

The WDP in a forward auction can be formulated as a binary program using the decision variables $x_i(S)$ which indicate whether the bid of the bidder i for the bundle S belongs to the allocation:

$$\begin{aligned} \max_{x_i(S)} \quad & \sum_{S \subseteq \mathcal{K}} \sum_{i \in \mathcal{I}} x_i(S) v_i(S) \\ \text{s.t.} \quad & \sum_{S \subseteq \mathcal{K}} x_i(S) \leq 1 \quad \forall i \in \mathcal{I} \quad (\text{WDP}) \\ & \sum_{S: k \in S} \sum_{i \in \mathcal{I}} x_i(S) \leq 1 \quad \forall k \in \mathcal{K} \\ & x_i(S) \in \{0, 1\} \quad \forall i, S \end{aligned}$$

The first set of constraints guarantees that any bidder can win at most one bundle, which is only relevant for the XOR bidding language. Without this constraint, bidders can win multiple bundles, which is referred to as an *OR bidding language*.

The XOR language is used because it is fully expressive compared to the OR language, that is, a bidder can express values for all possible subsets of items. Subadditive valuations, where a bundle is worth less than the sum of individual items, cannot be described appropriately without an exposure risk using the OR bidding language. The second set of constraints ensures that each item is only allocated once. Very early, it has been shown that the WDP (with an OR bidding language) is NP-hard by reducing it to the weighted set packing problem [15].

Theorem 1 [15]. *The decision version of the WDP with an OR bidding language is NP-complete, even if restricted to instances*

where every bid has a value equal to 1, and every bidder bids only on subsets of size of at most 3.

The same holds for an XOR bidding language, where bidders only bid on subsets of size of at most 2 [19]. The decision version of the WDP refers to the WDP, in which the auctioneer only wants to know, if there is an allocation with a revenue larger than a particular amount. Given those hardness results, one could try to approximate the WDP. Approximation algorithms are polynomial time algorithms with a provable performance guarantee on the deviation from the optimal solution. Unfortunately, it has been shown that for OR and XOR bidding languages, there are no polynomial algorithms that approximate the WDP within certain bounds. A comprehensive overview of complexity results in this area is given in Lehmann *et al.* [18].

There are, however, tractable cases if we restrict bids or valuations in a way that gives the bids a structure to allow for efficient solution methods. For example, the *goods are substitutes property* (aka. *substitutes condition*) leads to integral solutions of the LP-relaxation of the WDP.

Definition 1 [Substitutes condition [13]]. Bidder i considers the objects in $\mathcal{K}$ to be substitutes if for all $A \in \mathcal{K}$ and packages S and T not containing A , such that $S \subset T$, $v_i(S \cup \{A\}) - v_i(S) \geq v_i(T \cup \{A\}) - v_i(T)$

In other words, if items being sold are substitutes, the marginal value of obtaining a particular object A is smaller if the set of objects T already owned is larger than another set S . The substitutes condition would allow for additive valuations but not for complements or superadditive valuations, and will also play a role when determining ask prices in combinatorial auctions as discussed in the section titled "Combinatorial Auction Formats".

Theorem 2 [20]. *Let for all $i \in \mathcal{I}$ the bid values $v_i(S)$, $S \subseteq \mathcal{K}$ of the WDP with an XOR*

bidding language satisfy the substitutes condition, then the LP-relaxation of the WDP has an integral optimal solution.

A good overview of tractable cases of the WDP is provided in Mueller [21]. Unfortunately, the restrictions on tractable cases are so severe that auctioneers cannot rely on them in most applications of combinatorial auctions. Independent of this, extensive analyses of the empirical hardness of the WDP [22] illustrate that satisfactory performance can be obtained for problem sizes and structures occurring in practice. The problem sizes in many real-world applications have shown to be tractable within acceptable time limits [6].

Apart from bundle bids, other types of advanced bidding languages and respective auction formats have shown to be useful. In addition to traditional multiunit auctions, which allow for the specification of a price for a particular quantity, *volume discount bids* allow to specify supply curves, that is, unit prices for different quantities of an item sold. Suppliers can express economies of scale when bidding on very large quantities (e.g., \$500 per unit until 1000 units and \$450 per unit for more than 1000 units). Also here, buyers need to consider various business constraints when selecting such bids. For example, there might be limits on the spend per bidder or group of bidders, and upper and lower bounds on the number of winners. These side constraints, as well as limited capacity of suppliers, turn the WDP into a hard computational problem [23,24].

Multiattribute auctions allow bids on price and qualitative attributes such as delivery time or warranty. In contrast to request for quotes or tenders as they are regularly used in procurement, the purchasing manager specifies a scoring function that is used to evaluate bids. This enables competitive bidding with heterogeneous, but substitutable offers. Multi-attribute auctions differ in the types of scoring rules or functions used, and in the type of feedback that is provided to bidders. Depending on the type of bids submitted, and on the type of scoring function, the auctioneer faces different optimization problems [25].

STRATEGIC COMPLEXITY

In this section, we discuss about auction formats, which elicit bidders' preferences to an extent that the optimal solution to the WDP, that is, the economic efficient outcome can be selected by the auctioneer. As outlined in the first paragraph of this article, a central auction design objective is to obtain an *efficient allocation* $X^* = (S_1^*, \dots, S_n^*)$, where S_i^* is bidder i 's bundle in this allocation.

Definition 2 [Allocative efficiency]. Allocative efficiency is measured as the ratio of the total valuation of the auction outcome X to the maximum possible valuation of an allocation (i.e., the efficient allocation) X^* :

$$E(X) = \frac{\sum_{i \in \mathcal{I}} v_i \left(\bigcup_{S \subseteq \mathcal{K}: x_i(S)=1} S \right)}{\sum_{i \in \mathcal{I}} v_i \left(\bigcup_{S \subseteq \mathcal{K}: x_i^*(S)=1} S \right)}$$

Since typically in auctions the bidder valuations are not given and bidders have incentives to lie about their true preferences, strategic complexity is a concern in the design of combinatorial auctions. Strategic complexity is concerned with the effort it takes for a bidder to determine his optimal bidding strategies. In some auction formats bidders might not be willing to reveal their true preferences and rather speculate, which is one of the main sources of inefficiency in auctions.

Incentive compatibility and *strategy proofness* are properties that should lead bidders to reveal their true private valuations to an extent that the auctioneer can determine the efficient allocation, without the need for further speculation about other bidders' preferences. An auction is incentive compatible, if truthful revelation is a Bayes–Nash equilibrium. In other words, truth revelation is optimal for a bidder, if and only if, all other bidders in a game with uncertainty about the types of other bidders reveal their valuations truthfully. An auction is strategy proof, if truth revelation is a dominant strategy for bidders, that is, it is the bidder's best strategy independent of other bidders' types and

strategies. In these cases, the strategic complexity of an auction is reduced to a minimum and speculation is not necessary.

Traditional single-object auction theory distinguishes at least four different types of auction formats: first-price sealed bid, Dutch, English, and second-price sealed bid auctions [13]. The first-price sealed bid and the Dutch auction are strategically equivalent, as are the English and the second-price sealed bid. The second-price sealed-bid auction or Vickrey auction has a dominant strategy, and the same holds for a simple implementation of the English auction, in which the auctioneer is replaced by an upward ticking clock, and bidders cannot place jump bids, but only drop out at a certain price level. This is often referred to as a Japanese or clock auction. The clock auction can be described as iterative or ascending auction format, where a bidder learns about the willingness-to-pay of other bidders during the course of the auction. Efficiency in dominant strategies is a desirable property of auction mechanisms. There is a generalization of the second-price sealed bid auctions (aka. Vickrey-Clarke-Groves auction) to multiple-item auctions, which maintains its dominant strategy property (see section “Combinatorial Auction Formats”). It is not obvious that a generalization of the clock auction or any other iterative auction format has similar properties.

General equilibrium models have been developed in Economics to show that in markets with multiple items, the Walrasian price mechanism also known as *tâtonnement*, which uses item-level or linear prices, actually yields the efficient allocation [26] while communicating as few real variables as possible [27,28]. As a consequence, the First Welfare Theorem shows Pareto-efficiency of allocations obtained at those equilibrium prices. The *tâtonnement* works as follows: Prices are cried, and agents register how much of each good they would like to offer or purchase. No transactions and no production take place at disequilibrium prices. Then, prices are lowered for goods with positive prices and excess supply, and prices are raised for goods with excess demand until no agent wants to deviate from his allocation.

However, these results assume that all production sets and preferences are convex. The results do not carry over to nonconvex economies with indivisible items, such as they often occur in combinatorial auctions. The question is, whether a combinatorial auction mechanism can be fully efficient, and, if so, what types of equilibrium prices are necessary. We will introduce the notion of “Competitive Equilibrium” for the following discussion.

Definition 3 [Competitive equilibrium, CE [29]]. Prices $\mathcal{P}$, and allocation X^* are in competitive equilibrium if allocation X^* maximizes the payoff of every bidder and the auctioneer revenue given prices $\mathcal{P}$. The allocation X^* is said to be *supported* by prices $\mathcal{P}$ in CE.

The first approach would be to use the same Walrasian price mechanism and see if it produced efficient outcomes in combinatorial auctions, where indivisibilities are present. Unfortunately, without convexity assumptions full efficiency cannot be achieved with simple linear competitive equilibrium prices in a combinatorial auction with unrestricted bidder valuations. It has been shown that a CE always exists in combinatorial auctions, but it possibly requires nonlinear and nonanonymous prices [30,31]. Prices are *nonlinear* if the price of a bundle is not equal to the sum of prices of its items, and prices are *nonanonymous* or *personalized* if prices for the same item or bundle differ across bidders. This leads to the following classification of CE prices:

1. linear anonymous prices $\mathcal{P} = \{p(k)\}$
2. linear personalized prices $\mathcal{P} = \{p_i(k)\}$
3. nonlinear anonymous prices $\mathcal{P} = \{p(S)\}$
4. nonlinear personalized prices $\mathcal{P} = \{p_i(S)\}$

Indeed, there have been proposals for *ascending* combinatorial auctions with nonlinear and personalized prices, which have been shown to be fully efficient if bidders follow a straightforward bidding strategy [32]. Such a strategy assumes

that bidders bid only on those bundles, which maximize their payoff in each round. Unfortunately, straightforward bidding is only a best response for bidders in pure ascending combinatorial auction formats, if bidders' valuations are restricted (see section "Combinatorial Auction Formats").

More generally, it is known that the only efficient mechanisms in which honest revelation is a dominant strategy for each agent is the Vickrey-Clarke-Groves (VCG) mechanism [33]. VCG mechanisms, however, exhibit significant problems in practical applications [34,35]. Among others, the VCG mechanism can lead to low seller revenues, nonmonotonicity of the seller's revenues in the set of bidders, and is susceptible to collusion. Apart from this, all bidders would need to submit all their valuations for an exponential number of bundles, which is not practical for all but very small auctions with only a few items.

In summary, designing strategy-proof and practical combinatorial auction formats turns out to be a formidable task. The VCG auction does not seem practical in most applications and iterative forms of combinatorial auctions are bound to nonlinear and personalized competitive equilibrium prices for full efficiency.

COMBINATORIAL AUCTION FORMATS

In the following, we provide an overview of well-known combinatorial auction formats and discuss some of the concepts from the overview in the previous section in more detail.

The Vickrey-Clarke-Groves Auction

VCG mechanisms describe a class of strategy-proof economic mechanisms [36,37], where sealed bids are submitted to the auctioneer. The winners are also determined by the WDP. However, rather than paying the bid prices, the winners pay a discounted price. This price is calculated in the following manner.

$$p_i^{VCG} = v_i(X^*) - [w(\mathcal{I}) - w(\mathcal{I}_{-i})]$$

Here p_i^{VCG} describes the Vickrey price, while $w(\mathcal{I})$ is the objective value the WDP

with the valuations of all bidders, and $w(\mathcal{I}_{-i})$ is the objective value to the WDP with all bidders except the winning bidder i . If the auction is modeled as a coalitional game, $w(\bullet)$ can also be referred to as the *coalitional value function*, that is, the outcome of the auction game with a certain set of bidders. In a combinatorial auction, this means that a bidder needs to submit bids on all possible bundles, a number which is exponential in the number of items. Each winning bidder receives a Vickrey payment, which is the amount that he has contributed to increasing the total value of the auctioneer.

Let us take an example with two items x and y which are to be sold in a combinatorial auction. The bids of bidder 1 and 2 are described in Table 2. The total value will be maximized at \$34, while selling x to bidder 1 and y to bidder 2. Bidder 1 bids \$20 for x , but he receives a Vickrey payment of \$34 - \$29 = \$5, since without his participation the total value would be \$29. In other words, the net payment or Vickrey price p_1^{VCG} bidder 1 has to pay to the auctioneer is (\$20 (bid price) - \$5 (Vickrey payment) =) \$15. Bidder 2 bids \$14 on y , but receives a Vickrey payment of \$34 - \$33 = \$1, because without his participation the total valuation of this auction would be \$33. Auctioneer revenue would then be \$15 + \$13 = \$28 in this auction.

In this auction bidders have a dominant strategy of reporting their true valuations $b_i(S) = v_i(S)$ on all bundles S to the auctioneer, who then determines the allocation and respective Vickrey prices. As already introduced in the previous section, the VCG design suffers from a number of practical problems.

The decisive fault of the VCG is best understood if the auction is modeled as a coalitional game [34]. (N, w) is the coalitional game derived from trade between the seller and bidders. Let N denote the set of all bidders $\mathcal{I}$ plus the auctioneer with $i \in N$, and

Table 2. Bids Submitted in a VCG Auction

Items	Bids		
	{x}	{y}	{x,y}
Bidder 1	20*	11	33
Bidder 2	14	14*	29

Table 3. Bids Submitted in a VCG Auction

Items	Bids		
	$\{x\}$	$\{y\}$	$\{x, y\}$
Bidder 1	0	2	2
Bidder 2	2	0	2
Bidder 3	0	0	2

$M \subseteq N$ be a coalition of bidders with the auctioneer. Let $w(M)$ denote the coalitional value for a subset M , equal to the objective value of the WDP with all bidders $i \in M$ involved. A core payoff vector Π , that is, payoffs Π_i of the bidders in this auction, is then defined as follows

$$\text{Core}(N, w) = \left\{ \Pi \geq 0 \mid \sum_{i \in N} \pi_i = w(N), \right. \\ \left. \sum_{i \in M} \pi_i \geq w(M) \quad \forall M \subset N \right\}$$

This means, there should be no coalition $M \subset N$, which can make a counteroffer that leaves themselves and the seller at least as well off as the currently winning coalition. Unfortunately, in the VCG auction there can be outcomes which are not in the core. To see this, assume again a combinatorial sales auction with three bidders and two items (see Table 3).

Bidder 1 bids $b_1(x) = \$0$, $b_1(y) = \$2$ and $b_1(x, y) = \$2$. Bidder 2 bids $b_2(x) = \$2$, $b_2(y) = \$0$ and $b_2(x, y) = \$2$. Finally, bidder 3 only has a bid of $b_3(x, y) = \$2$, but no valuation for the individual items. In this situation the net payments of the winners (bidder 2 and 3) are zero, and bidder 3 could find a solution with the auctioneer that makes both better off. It has been shown that there is an equivalence between the core of the coalitional game and the competitive equilibrium for single-sided auctions [31]. Outcomes, which are not in the core lead to a number of problems, such as low seller revenues or nonmonotonicity of the seller's revenues in the set of bidders and the

amounts bid. To see this, just omit bidder 1 from the auction. Also, such auction results are vulnerable to collusion by a coalition of losing bidders. Therefore, it has been argued that the outcomes of combinatorial auctions should be in the core [38].

The *bidders are substitutes condition* (BSC) is necessary and sufficient to support VCG payments in competitive equilibrium [31]. A bidder's payment in the VCG mechanism is always less than or equal to the payment by a bidder at any other CE.

Definition 4 [Bidders are Substitutes Condition, BSC]. The BSC condition requires

$$w(N) - w(N \setminus M) \geq \sum_{i \in M} [w(N) - w(N \setminus i)], \\ \forall M \subseteq N$$

In other words, BSC holds where the incremental value of a subset of bidders to the grand coalition is at least as great as the sum of the incremental contributions of each of its members. When at least one bidder has a nonsubstitutes valuation an ascending CA cannot implement the VCG outcome [39].

Nonlinear Personalized Price Auctions

In this section, we discuss relevant theory with respect to ascending combinatorial auctions using nonlinear and personalized prices (NLPPAs). We have seen that the WDP is a nonconvex optimization problem. By adding constraints for each set partition of items and each bidder to the WDP the formulation can be strengthened, so that the integrality constraints on all variables can be omitted but the solution is still always integral [31, 39]. Such a formulation describes every feasible solution to an integer problem, and is solvable with linear programming. We will refer to this formulation as NLPPA WDP.

$$\begin{aligned} \max \quad & \sum_{i \in \mathcal{I}} \sum_{S \subseteq \mathcal{K}} v_i(S) x_i(S) \\ \text{s.t.} \quad & x_i(S) = \sum_{X: x_i = S} \delta_X \quad \forall i \in \mathcal{I}, \forall S \subseteq \mathcal{K} \quad (p_i(S)) \\ & \sum_{S \subseteq \mathcal{K}} x_i(S) \leq 1 \quad \forall i \in \mathcal{I} \quad (\pi_i) \\ & \sum_{X \in \Gamma} \delta_X = 1 \quad (\pi^s) \\ & 0 \leq x_i(S) \quad \forall S \subseteq \mathcal{K}, \forall i \in \mathcal{I} \\ & 0 \leq \delta_X \quad \forall X \in \Gamma \end{aligned} \quad \text{(NLPPA WDP)}$$

Personalized nonlinear CE prices can now be derived from the dual of the NLPPA WDP. In the first side constraint, $x_i(S)$ is equal to the sum of weights δ_X over all allocations X where bidder i gets bundle S . The dual variables of this constraint are the personalized prices $p_i(S)$. The second side constraint makes sure that each bidder i receives at most one bundle, and the dual variable π_i describes bidder i 's payoff. Finally, the total weight of all selected allocations $X \in \Gamma$ equals 1, such that only one allocation can be selected. Here, Γ describes the set of all possible allocations. The dual variable (π^s) for this side constraint describes the seller's payoff.

From duality theory follows that the *complementary slackness conditions* must hold in the case of optimality. This is equivalent to the CE, where every buyer receives a bundle out of his demand set or demand correspondence $D_i(\mathcal{P})$, that is, the bundles maximizing his payoff at the prices, and the auctioneer selects the revenue maximizing allocation at these prices.

Definition 5 [Demand set]. The demand set $D_i(\mathcal{P})$ of a bidder i includes all bundles which maximize a bidder's payoff π_i at the given prices $\mathcal{P}$:

$$D_i(\mathcal{P}) = \left\{ S : \pi_i(S, \mathcal{P}) \geq \max_{T \subseteq \mathcal{K}} \pi_i(T, \mathcal{P}), \right. \\ \left. \pi_i(S, \mathcal{P}) \geq 0, S \subseteq \mathcal{K} \right\}$$

Complementary slackness provides us with an optimality condition, which also serves as a termination rule for NLPPAs. If bidders follow the straightforward strategy then terminating the auction when each active bidder receives a bundle in his demand set will result in the efficient outcome. Note that a demand set can include the empty bundle. In addition, the starting prices must represent a feasible dual solution. A trivial solution is to use zero prices for all bundles.

Although such nonlinear personalized prices always exist, the NLPPA WDP is huge since one must enumerate all possible feasible coalitions. Nevertheless, it has

provided a guideline to a number of practical auction designs using nonlinear personalized prices. Individual NLPPA formats discussed in the following such as the Ascending Proxy Auction, iBundle, and the dVSV auction have different rules for determining the prices provided to the bidders and for determining how bidders submit new bids based on these announced prices.

iBundle [40] calculates a provisional revenue maximizing allocation at the end of every round and increases the prices based on the bids of nonwinning bidders. Three different versions of iBundle have been suggested [40]: iBundle(2) with anonymous prices, iBundle(3) with personalized prices, and iBundle(d) that starts with anonymous prices and switches to personalized prices for agents who submit bids for disjoint bundles. The *ascending proxy auction* [32] is similar to iBundle(3), but the use of proxy agents is mandatory, which essentially leads to a sealed-bid auction format.

The dVSV auction [39] design differs from iBundle in that it does not compute a provisional allocation in every round but increases prices for one *minimally undersupplied set of bidders*. A set of bidders is minimally undersupplied if each bidder in this set receives a bundle from his demand set, and removing only one of the bidders from the set forfeits this property. Similar to iBundle(3), it maintains nonlinear personalized prices and increases the prices for all agents in a minimally undersupplied set based on their bids of the last round. While the Ascending Proxy Auction can be interpreted as a sub-gradient algorithm, the dVSV auction can be interpreted as a primal-dual algorithm for the NLPPA WDP [39].

Even though the BSC condition is sufficient for VCG prices to be supported in CE, the slightly stronger *bidder submodularity condition (BSM)* is required for a pure ascending combinatorial auction to implement VCG payments [39].

Definition 6 [Bidder submodularity condition, BSM]. BSM requires that for all $M \subseteq M' \subseteq N$ and all $i \in N$ there is

$$w(M \cup \{i\}) - w(M) \geq w(M' \cup \{i\}) - w(M')$$

Here bidders are more valuable, when added to a smaller coalition. Under BSM the NLPPAs yield VCG payments and straightforward bidding is an ex post equilibrium. An ex post equilibrium is stronger than a Bayes-Nash equilibrium, but weaker than a dominant strategy equilibrium. It does not require bidders to speculate about other bidders' types, but requires assumptions about their strategies. When the BSM condition does not hold, the property breaks down and a straightforward strategy is likely to lead a bidder to pay more than the VCG price for the winning bundle, and bidders have an incentive to shade their bids and deviate from straightforward bidding. In case of nonstraightforward bidding the outcome of NLPPAs can deviate significantly from the efficient solution [41].

The restriction to BSM valuations is mainly due to the definition of ascending auctions, such that prices can only increase and no payments from the auctioneer are allowed. The *Credit-Debit auction* is an extension to the dVSV design which achieves the VCG outcome for general valuations by determining payments or discounts from the auctioneer to the bidders at the end. Similarly, *iBEA* is described as an extension of iBundle. Both approaches are based on universal competitive equilibrium (UCE) prices, which are CE prices for the main economy as well as for every marginal economy, where a single buyer is excluded [42]. These auctions terminate as soon as UCE prices are reached and VCG payments are determined as one-time discounts dynamically during the auction. Truthful bidding is an ex post equilibrium in the Credit-Debit auction and iBEA. The auctions are an important contribution to the literature, because they describe fully efficient iterative combinatorial auctions where straightforward bidding is an ex post equilibrium for general valuations. However, they share a central problem of the VCG auction: if buyer submodularity does not hold, the outcomes might not be in the core.

Linear Price Auctions

In many applications of ICAs, linear and anonymous ask prices are essential. For

example, day-ahead markets for electricity sacrifice efficiency for the sake of having linear prices [43]. Also, the main auction formats, which have been tested for selling spectrum in the United States used linear ask prices [44]. Simple examples illustrate that linear anonymous CE prices do not exist for general valuations. It has been shown that the *goods are substitutes* property is a sufficient condition for the existence of the exact linear CE prices [20], as the LP-relaxation of the WDP is integral (see "Computational Complexity") and dual variables can be interpreted as prices. The substitutes condition is, however, very restrictive and not satisfied in most combinatorial auctions. In spite of these negative results, some combinatorial auction designs with linear prices achieved high levels of efficiency in the lab.

The *CCA* (combinatorial clock auction) [45] utilizes anonymous linear ask prices called *item clock prices*. In each round bidders express the quantities desired on the bundles at the current prices. As long as demand exceeds supply for at least one item (each item is counted only once for each bidder) the price clock "ticks" upwards for those items (the item prices are increased by a fixed price increment), and the auction moves on to the next round. If there is no excess demand and no excess supply, the items are allocated corresponding to the last round bids and the auction terminates. If there is no excess demand but there is excess supply (all active bidders on some item did not resubmit their bids in the last round), the auctioneer solves the WDP considering all bids submitted during the auction runtime. If the computed allocation does not displace any bids from the last round, the auction terminates with this allocation, otherwise the prices of the respective items are increased and the auction continues. Note that due to the winner determination the final payments can deviate from the ask prices.

The *RAD* (resource allocation design) proposed in Kwasnica *et al.* [46] uses anonymous linear ask prices. However, instead of increasing the prices in case of over-demand, the auction lets the bidders submit

priced bids and calculates so called pseudo-dual prices based on a restricted dual of the LP relaxation of the WDP [7]. The dual price of each item measures the cost of not awarding the item to whom it has been allocated in the last round. In each round the losing bidders have to bid more than the sum of ask prices for a desired bundle plus a fixed minimum increment. RAD suggests an OR bidding language and only winning bids remain in the auction in its original design. The *ALPS* (approximate linear prices) design [47] is also based on the ideas in Rassenti *et al.* [7], but improves termination rules and the ask price calculation to better balance prices across items and have the auction avoid cycles. Note that in RAD and ALPS, prices can also decrease if the competition shifts to different items.

HPB (hierarchical package bidding) imposes a hierarchical structure of allowed package bids. This hierarchy and an OR bidding language reduces the WDP to a computationally simple problem that can be solved in linear time [15]. If the hierarchy meets the bidder's preferences, the auction is likely to achieve efficient outcomes, and reduces the strategic complexity for bidders. HPB provides a simple and transparent pricing mechanism [48]. It uses a recursive algorithm to determine new ask prices, which starts with the highest bids on every single item as a lower bound, adding a tax if the next level package received a bid higher than the sum of the single item bids contained in the package. The difference is distributed uniformly upon the respective item prices. The algorithm ends evaluating the package(s) of the top level, resulting in new ask prices for each item.

A few other combinatorial auction designs have been suggested, which use linear and nonlinear prices. For example, in the Clock-Proxy auction a clock auction is followed by a best-and-final ascending proxy auction [49]. The approach combines the simple and transparent price discovery of the clock auction with the efficiency of the ascending proxy auction. Progressive adaptive user selection environment (PAUSE) combines the simultaneous multiround auction with bidding on bundles in later

stages. Here, the burden of evaluating a combinatorial bid is transferred to the bidder [50]. Also, alternative ways of pricing and bidder support have shown promising results [51].

Interestingly, experimental research has shown that iterative auction designs with linear prices achieved very high levels of efficiency, even for auctions with up to 18 items [44,48,52]. While linear competitive equilibrium prices do not always exist, linear ask prices used in the combinatorial clock auction [45], HPB [48], or ALPS [47] have shown to be a good guideline to bidders in finding the efficient solution, even though no formal equilibrium analysis is available for any of these auction formats.

CONCLUSIONS

Many theoretical results on combinatorial auctions are negative in the sense that it seems quite unlikely that practical applications would satisfy the assumptions, which would lead to efficiency with a strong game-theoretical solution concept. Nevertheless, experimental results have yielded very high levels of efficiency in the lab. These results suggest that even if full efficiency is not always possible, combinatorial auction designs can achieve very high levels of efficiency, higher than what would be possible in simultaneous or sequential auctions in the presence of complementarities. The results of this research can have significant impact on the design and the efficiency of real-world markets. Further development of practical combinatorial auction designs will probably remain an active and rewarding area of theoretical, experimental, and applied research for the foreseeable future.

COMBINATORIAL AUCTIONS

INTRODUCTION

A combinatorial auction is a resource allocation process that can be implemented when multiple resources must be simultaneously allocated amongst competing users, and information concerning the values of the various possible uses and constraints affecting those uses is decentralized. For example, the demands for landing and takeoff “slots”¹ at LaGuardia airport in New York outstrip the maximum 45 arrivals per hour servicing constraint. To ensure safety at LaGuardia and to control demand, the Port Authority of New York requires that airlines have in their possession a designated takeoff or landing slot that they have issued prior to time of use. Now imagine that congested airspace becomes a simultaneous reality at many major airports (various reports indicate this day will soon be upon us), and the slot-based regime becomes enforced by all airport authorities. In order to determine the *efficient* (value maximizing) allocation of landing and takeoff slots to competing airlines across the country, the “allocation center” would need to solve the following set packing problem with added logistical constraints²

Maximize : $Z = \sum_j \pi_j x_j \rightarrow$ Maximize the
value of the allocated slots (1)

¹A takeoff/landing slot is usually thought of as a 15 min interval during which a maximum number of airplanes can safely takeoff and/or land.

²One can think of the vector $\langle \pi_j, a_{ij}, d_{kj}, e_k \rangle$ as a bid submitted by an airline.

Subject to : $\sum_j a_{ij} x_j \leq b_i \quad \forall i \rightarrow$ Maximum
number of slots available
imposed by airports (1a)

$\sum_j d_{kj} x_j \leq e_k \quad \forall k \rightarrow$ Logical constraint
on packages imposed airlines
(1b)

$x_j \in \{0, 1\} \rightarrow$ Either the whole package
is accepted or not.

Where:

- $i = 1, \dots, N$, subscripts some particular
takeoff or landing slot at some
particular airport;
- $j = 1, \dots, J$, subscripts some package of
slots that has value for some
particular airline³;
- $k = 1, \dots, K$, subscripts some particular
logistical constraint imposed on a set
of packages by some airline or by the
optimizing center⁴;

³An airline is always interested in combinations (packages) of slots to optimize their own flight resources. A landing slot without a corresponding takeoff slot at a particular airport would be of very little value. Furthermore, a particular aircraft is most efficiently used when it cycles through a series of takeoffs and landings in a given day or set of days. If slots were not allowed to be sold in useful combinations but had to be procured piecemeal (slot by slot and airport by airport), then an airline would face the considerable financial exposure of paying too much for a noncomplementary sets of slots (see Bykowsky *et al.* [1] for more on financial exposure in noncombinatorial auctions).

⁴For example, suppose an airline has one airplane and a value π_z for using it with the cycle of slots in package z , and π_y for using it with the cycle of slots in package y which occurs 30 min later. Then the airline would specify its interest in obtaining package z or y but not both, by submitting the logical constraint $x_z + x_y \leq 1$ to the center. Similarly, the center might wish to impose constraints on allocations to potential users: for example, user u should not be allocated the rights to any more than s slots at airport a .

$$a_{ij} = \begin{cases} 1 & \text{if package } j \text{ includes slot } i \\ 0 & \text{otherwise;} \end{cases}$$

b_i = the number of planes that can takeoff (land) in slot i at some airport;

$d_{kj} \in \{-1, 0, 1\}$, if package j appears in logistical constraint k ⁵;

e_k = an integer;

π_j = the value of obtaining slot package j to the airline that seeks it.

While this is a difficult (but manageable) discrete programming problem, the real problem is that π_j (the value of package j to the airline that seeks it), a_{ij} (whether a particular slot is included in package j), and d_{kj} (whether package j is part of some logistical constraint k) are all parameters that are not known to the “allocation center” but privately known to the competing airlines. That is, the center needs to solve a resource allocation problem where information on the coefficients in the objective function and constraints is decentralized and unknown, except for what may be revealed voluntarily by the potential users during the auction process.

AUCTION DESIGN

Each auction process requires users to supply information to the “optimizing center,” in order to be included in the final allocation. The incentive problem in mechanism design⁶ refers to the process in determining who is allocated which resources at specific prices so that the quality of information provided by users can be used by the center to obtain a desired outcome. The most famous of such mechanisms is the Vickrey auction [3]. This sealed-bid auction uses a

particular pricing scheme to provide users the incentive to reveal truthful information. While Vickrey did not develop his original auction for package bids, his basic principles are easily extended to cover many cases where users would compete for packages of resources subject to user and/or system specific constraints.⁷

For example, in Maximization (1), suppose airline $\mathcal{L}$ submits a vector of bids for L different packages of slots. (Without loss of generality, assume the first L of all J bids recorded by the system are those belonging to airline $\mathcal{L}$.) The Vickrey auction has two parts. First, using all J submitted sealed bids and any constraints imposed on the bids by the airlines or the center, we solve Maximization (1) above and obtain the maximum revenue Z^* and the corresponding allocation $\mathbf{x}^*$ of slot packages to airlines. The next step, crucial in soliciting truthful bid information, is to determine the total price for each auction winner in an incentive compatible manner. The total Vickrey price for all packages j won by airline $\mathcal{L}$ ($j \in \{1, \dots, L\}$) is found by performing the following calculations:

- Remove ALL of airline $\mathcal{L}$ ’s bids and constraints from the system and recalculate the solution to Maximization (1) using all remaining bids and constraints but not $\mathcal{L}$ ’s. Let $Z \sim$ denote the optimal value of the bids without $\mathcal{L}$ ($\sim \mathcal{L}$), and let $\mathbf{x} \sim$ denote the allocation using $\sim \mathcal{L}$.
- Airline $\mathcal{L}$ then pays the following total price $p_{\mathcal{L}}$ for all its winning bids:

$$\begin{aligned} p_{\mathcal{L}} &= \sum_{j=1, L} \pi_j x_j^* - [Z^* - Z \sim] \\ &= Z \sim - \sum_{j=L+1, J} \pi_j x_j^*. \end{aligned} \quad (2)$$

There are two interesting things to note: first, that the total paid for the airline $\mathcal{L}$ ’s winning bids is always less than or equal to the total amount that it bid ($\sum_{j=1, L} \pi_j x_j^*$); and second, that the airline’s bids do not

⁵As an example of a logical constraint suppose we have $e_k = 2$ and $d_{k1} = -1$; $d_{21} = 1$; $d_{31} = 1$ for some k so that we have a constraint $-x_1 + x_2 + x_3 \leq 1$. This means that a necessary condition for both packages 2 and 3 to be part of the solution is that package 1 must also be part of the solution; otherwise, only one of packages 2 or 3 can be included.

⁶See Myerson [2] for more on mechanism design.

⁷See Forsythe and Isaac [4] for an example. In addition, Jackson [5] developed a Vickrey auction for the vertex picking problem, a combinatorial problem.

determine its payment (the RHS of the price calculation involves only the bids $j = L + 1, \dots, J$). Because of these properties, the incentive structure of this auction provides a dominant strategy for the airline to truthfully reveal all its package value information.

At first glance it seems then that we need not proceed any further: the Vickrey auction appears to be the panacea for complex resource allocation problems with decentralized value information. But, though the Vickrey auction has this nice revelation property, it is plagued by several other issues that can cause it to be shunned for field implementation. For this introduction, we discuss a couple of specific shortcomings.⁸ First, it should be noted that Maximization (1) is an NP-complete problem. This is known in the auction literature as the winner-determination problem or, as Michael Rothkopf calls it, the 2^N bogeyman, where N is the number of different resources available for allocation in Maximization (1).⁹ In addition, each price determination is also a 2^N problem. Furthermore, each potential user must determine how many of the 2^N possible bids it should submit.¹⁰ Second, Vickrey prices are not linear in the sense that most users would be familiar with, where each slot (resource) would have its own price. Prices normally perform the very important task in a resource constrained economy of signaling scarcity and value. No price discovery is provided in the Vickrey auction. In the experimental economics literature, it is well documented that auctions that provide feedback and price adjustment, such as the English

auction, perform better than sealed-bid auctions that have no feedback mechanism.¹¹ Third (and importantly!), the Vickrey prices can often bring the center very low amounts of revenue.¹² Fourth, the winning allocations are nonmonotonic in the sense that adding more competition to the Vickrey auction can actually reduce prices and revenue.¹³ And finally, the Vickrey auction does not handle budget constraints well. They require the submission of some large set of side constraints, and not being able to express the true value for a package if its value exceeds a bidder's auction budget can also eradicate the dominant strategy to reveal the truth concerning the value of all packages.

With these shortcomings of the Vickrey auction in mind, we investigate the evolving design of combinatorial auctions that developed to be better suited for field implementation when human agents are bid competitively for the rights to use scarce resources.

COMBINATORIAL AUCTION DESIGN

Finding Slot Prices

The term combinatorial auction was coined by Rassenti, Smith, and Bulfin (RSB), when they first designed and tested an auction for takeoff and landing slots by allowing participants to bid for packages of slots [11].¹⁴ If Maximization (1) were a linear programming

⁸For more details on the other issues with the Vickrey auction see Ausubel and Milgrom [6] and Rothkopf *et al.* [7].

⁹The 2^N is a worst-case scenario. There are useful approximation algorithms that could be used for winner-determination [8]. How such approximating algorithms would perform in a strategic setting is yet to be determined.

¹⁰Practitioners well know that explaining Vickrey pricing rules and allocations to bidders is difficult (Parkes [9] calls this feature *transparency* of the auction design).

¹¹For example, see Smith *et al.* [10].

¹²For example, suppose there are two items to be allocated A and B and User1 is willing to pay \$10 for item A, User2 is willing to pay \$10 for item B, and User3 is willing to pay \$11 for both items A and B. Then the winners would be User1 and User2, and according to Equation (2), they would each pay a Vickrey price of \$1.

¹³Even more troublesome in the example of the previous footnote is that if User1 reduced his willingness to pay for A, say from \$10 to \$4, then User1 would still pay \$1 but User2 would pay \$7, increasing the center's revenue.

¹⁴For more detailed information on combinatorial auctions, see Vries and Vohra [12].

problem, then the dual of Maximization (1) would provide shadow prices for slots. However, integer programs do not normally allow the dual program to find the linear shadow prices for each resource, which completely separate winning from losing bids.¹⁵ However, in keeping with the real-world norm for implementing processes that provide bidders and the center price discovery during resource allocation processes, RSB were interested in devising a way to price individual slots that provided users feedback on their scarcity, and simultaneously provided airports a method to divide the income from the auction. The RSB process allowed airlines to submit package bids of the form as described in Maximization (1), and then used these bids to find the revenue maximizing allocation $(Z^*, \mathbf{x}^*)$. Let $\mathcal{A} = \{j | x_j^* = 1\}$ be the set of accepted bids, and $\mathcal{R} = \{j | x_j^* = 0\}$ be the set of rejected bids given by this solution.

The pricing algorithm implemented required solving a complementary set of pseudo-dual linear programs. Program D_R defined the set of linear prices w_i one for each slot i , such that if $\pi_j > \sum_i w_i a_{ij} x_j$ then the package j was definitely accepted ($j \in \mathcal{A}$):

$$\begin{aligned} & \text{Minimize : } \sum_R y_r \\ & \text{Subject to : } \sum_i w_i a_{ij} \leq \pi_j \quad \forall j \in \mathcal{A} \\ & \quad y_r \geq \pi_r - \sum_i w_i a_{ir} \quad \forall r \in \mathcal{R} \quad (D_R) \\ & \quad y_r \geq 0, w_i \geq 0. \end{aligned}$$

Program D_A defines the set of prices v_i one for each slot i , such that if $\pi_r < \sum_i v_i a_{ir} x_r$ then the package r was definitely rejected ($r \in \mathcal{R}$):

$$\begin{aligned} & \text{Minimize : } \sum_A y_j \\ & \text{Subject to : } \sum_i v_i a_{ir} \leq \pi_r \quad \forall r \in \mathcal{R} \\ & \quad y_j \geq \sum_i v_i a_{ij} - \pi_j \quad \forall j \in \mathcal{A} \quad (D_A) \\ & \quad y_j \geq 0, v_i \geq 0. \end{aligned}$$

¹⁵There are infrequent exceptions which occur when the linear solution to Maximization (1) happens to correspond to an integer solution and a competitive equilibrium exists with separating prices.

RSB used these prices as if they were competitive equilibrium prices, so that for $\pi_j \geq \sum_i w_i a_{ij} x_j$ the winning bidder would pay the w_i prices for the individual slots in the package j . If package k was in the solution to Maximization (1) but $\sum_i w_i a_{ik} x_k \geq \pi_k \geq \sum_i v_i a_{ij} x_j$, then the winning bidder would pay exactly his bid of π_k . RSB tested this simple combinatorial auction process in a laboratory setting across repeated rounds of bidding, and found that it had reasonable incentive properties and very high levels of allocative efficiency when compared to independent auctions for each slot which later required the participants to assemble their own packages. Unfortunately, this is a sealed-bid auction, so there can only be feedback across auctions, and there is no price discovery within an auction. In addition, the 2^N bogeyman was not directly confronted in this design as participants had value for a very limited set of packages and budget constraints were not an issue.

Auctions with Feedback

Banks *et al.* [13] try to solve Maximization (1) using a combinatorial English auction.¹⁶ This auction format allows participants to individually place public bids for packages of items. When a bid is submitted, the center checks to see if the bid can be added to the standing allocation; if not, it goes into a queue where other bidders can view and combine with it to displace standing bids. Table 1 provides an example of this process.

Notice that there is no computational problem for the center here. The entire computational burden is placed on the bidders to find combinations that can displace standing bids. The main feature of this design is the feedback and open package price discovery during the bidding process.

¹⁶The typical English auction is an open outcry process in which the auctioneer accepts increasingly higher bids “from the floor” delivered by participants. The highest bidder at any given moment defines the standing bid, which can only be displaced by a higher bid from another participant. If no participant betters the standing bid within a fixed time, the standing bid becomes the winning bid.

Table 1. Combinatorial English Auction

<i>Standing Bids (Contract 1)</i>			
Bidder	Item X	Item Y	Bid(\$)
1	15	2	50
4	1	10	75
5	4	8	100
	20	20	
↓			
<i>Standby Queue</i>			
Bidder	Item X	Item Y	Bid(\$)
8	5	4	40
↓			
<i>New Potential Bid</i>			
Bidder	Item X	Item Y	Bid(\$)
6	11	8	120
↓			
<i>Combined 8+6 Value</i>			
Bidder	Item X	Item Y	Bid(\$)
8	5	4	40
6	11	8	120
	16	12	160
	20	20	
⇒			
<i>New Standing Bids (Contract 2)</i>			
Bidder	Item X	Item Y	Bid(\$)
8	5	4	40
6	11	8	120
5	4	8	100

The system has 20 units of X and 20 units of Y available for sale. Currently bidder 1 has a bid for 15 units of X and 2 units of Y , and is willing to pay \$50 for that package. Bidders 4 and 5 also have standing bids for packages. The current bids exhaust the available resources. Bidder 8 submits a bid for 5 units of X and 4 units of Y for \$40. This cannot displace any of the standing bids alone unless Bidder 8 raises his bid to more than \$125. Thus, his bid is sent to the standby queue. Bidder 6 sees the Bidder 8 bid and tenders a bid for 11 units of X and 8 units of Y for which he is willing to pay \$120. Together, Bidders 6 and 8 displace Bidders 1 and 4, since their combined bid is higher and fits within the released resources. The new set of bids now become the standing bids.

However, this auction has high cognitive participation costs. More importantly, there is no individual price information to guide decision making. There is no transparency provided to the bidder concerning the minimum amount they need to bid to be included in the optimal allocation. That is, each tentative bidder needs to solve their own 2^N problem in order to understand how to combine properly with existing bids in both the queue and the standing contract.

Subsequent to this design, many other iterative auctions sprang up responding to the need to examine such auction processes in preparation for the allocation of the radio spectrum by the Federal Communications Commission (FCC). This seemed to be an excellent potential use for a combinatorial auction. Indeed, the interest in combinatorial

auctions has mushroomed since the late 1990s as auctions have become the preferred method for the allocation of spectrum around the world. Several extensions of the English auction for package bids have been developed.¹⁷

One auction that reduces the computational burden on bidders but provides feedback is the iBundle mechanism developed by Parkes [15]. This auction proceeds in rounds $t = 1, 2, \dots$, where in each round participants are permitted to submit bids that have an exclusive OR logic: that is, only one of the submitted bids can be accepted in the final allocation. iBundle keeps track of all

¹⁷See Cramton *et al.* [12] and de Vries and Vohra [14] for examples.

submitted bids and the highest bid submitted on a package becomes the ask price for that package. For example, Maximization (1) is solved using the bids, where the bids of each participant are OR bids. The solution to Maximization (1) then becomes the provisional allocation to be bettered. The “ask prices” for round $t + 1$ are the best bids on each package from round t plus an increment. Bids for packages in round $t + 1$ are considered competitive if they meet the ask price. The auction ends when each competitive bidder receives one package (this could be the null package). The basic feature of iBundle, and a typical feature of most iterative mechanisms, is that there is feedback on what makes a particular package bid competitive during the auction process. However, there remains a 2^N optimization problem to solve each round, and a large cognitive load to determine whether my bid might be a winner in the next round when the next optimization is solved.

Auctions with Item Price Feedback

In an attempt to select prices for each item to help guide bidders in an iterative combinatorial auction, Kwasnica *et al.* [16] devised a set prices, one for each item, that determine whether a bid submitted in round t is acceptable. This auction is called the *resource allocation design* or *RAD*. Using prices for the elemental goods, it becomes easy for a bidder to determine the minimum bid required for a package to be acceptable by simply adding the prices of each item in the package. Returning to Maximization (1), the task is to find a set of prices v_i one for each slot $i = 1, \dots, m$ that can guide bidders and move the auction.¹⁸ RAD was motivated as an attempt to improve the noncombinatorial auction process used by the FCC to auction spectrum.¹⁹

RAD proposed three properties that prices must satisfy if bidders were to pay

them: (i) all accepted bids would receive price signals with aggregate costs totaling less than or equal to what they bid; (ii) all rejected bids would receive price signals that resulted in aggregate costs totaling higher than what they bid; and (iii) new bids willing to pay more than the aggregate price of the package should have a good opportunity to become provisionally winning (that is, prices ought to “guide” new bids to packages that will increase revenues). As discussed in RSB, (i) and (ii) are generally impossible to solve simultaneously, so these guidelines can only be executed in an approximate manner.

RAD proceeds in rounds $t = 1, 2, \dots$. In round t , Maximization (1) is solved using the round t submitted bids to generate the current optimal allocation $(^tZ^*, ^tx^*)$ with the set of winning bids $^t\mathcal{W} = \{j | ^tx_j^* = 1\}$ and the set of losing bids $^t\mathcal{L} = \{j | ^tx_j^* = 0\}$. RAD prices tv are then found by solving the following linear program:

$$\begin{aligned} \text{Minimize: } & D(D, ^tv, \mathbf{g}) \\ \text{Subject to: } & \sum_i ^tv_i a_{ij} = ^t\pi_j \quad \forall j \in ^t\mathcal{W} \\ & \sum_i ^tv_i a_{ij} \geq ^t\pi_j - g_j \quad \forall j \in ^t\mathcal{L} \quad (5) \\ & 0 \leq g_j \leq D \quad \forall j \in ^t\mathcal{L} \\ & ^tv_i \geq 0 \quad \forall i. \end{aligned}$$

The solution to program (5) ensures that at prices tv_i the winner of any package j pays his bid, and the variables g_j are selected so that all losing bids are less than their corresponding package prices with the maximum price distortion (D) minimized.²⁰ RAD does not ensure unambiguous price signals (a losing bid can exceed the sum of the prices of items of that package), and the winner-determination problem still looms in each round.

Clock Auctions and Item Price Feedback

One deficiency with iterative auctions in which participants select a bid π_j for their package j is that they do not know how to

¹⁸Recall that Rassenti *et al.* found a pseudo-dual envelope of prices for a single round sealed-bid. These prices could also be used in an iterative auction.

¹⁹See Milgrom [17] for a description of the basic FCC auction design.

²⁰The auction ends when there is no bid greater than the costs defined by the implicit prices.

refine their bids in order to not overshoot competitive prices. McCabe *et al.* [18] found “jump bidding behavior” in their attempts to test Vickrey’s proposal to use English auctions for multiple units. They found that allowing bidders to announce bid prices from the floor is not a good design feature in multiple unit auction environments as it can lead impatient bidders to overshoot competitive prices or aggressive bidders to deliver implicit signals to competitors. One way to eliminate this “strategic” behavior in the bid message space is to use clocks that move price upward automatically based on excess demand for each resource. With a clock-controlled resource price, the bidders need to announce only the quantity of the resource they wish to obtain at the current price. The bidder’s decision is relegated to a much simpler task, and the scope for strategic behavior is dampened significantly. Porter, Rassenti, Roopnarine and Smith (PRRS) extend the notion of a clock auction to a combinatorial environment and report experimental results with high levels of performance [19]. Their idea is simple. Returning to Maximization (1), for each slot $i = 1, \dots, m$ a price ${}^t v_i$ is posted in round $t = 1, 2, \dots$. At the stated clock prices, the participants submit the set of package bids they would be willing to pay for and attach any corresponding constraints (e.g., I’ll pay for package f or g but not both). The center keeps this information on record for each round t , and proceeds as follows:

1. Calculate the current excess demand ${}^t q_i$ for each item i .²¹
2. If ${}^t q_i > b_i$, set ${}^{t+1} v_i \leftarrow {}^t v_i + {}^t \varepsilon_i$; otherwise, set ${}^{t+1} v_i \leftarrow {}^t v_i$.

²¹PRRS counts a bidder’s overlapping packages as contributing multiple units of demand on the overlapped resources. This tends to lead bidders to avoid competition with themselves through round by round submission of a single large package aggregating their most valuable cover, but bidders must remain cognizant of the fact that providing the center discrete alternatives (often overlapping) increases the probability of matching with other bidders when a bidder cannot afford to outbid all others for a large package of resources.

The clock ticks up the price of resource i by ${}^t \varepsilon_i$ in round $t + 1$ if all bidders in aggregate demand more units of resource i than the center has available (b_i) to allocate. The price increment ${}^t \varepsilon_i$ need not be the same for all resources and it need not remain the same during the auction process for any given resource. In the PRRS auction, no information concerning excess demand or how the increments ${}^t \varepsilon_i$ are chosen is provided to the bidders: this makes tacit collusion a very difficult sport. Notice also that there is no winner-determination algorithm required to be run during each round of the auction process. The cognitive costs for the bidder are low and the process is intuitive: participants need only to understand their own private values for packages of the resources being offered. They do not need to estimate what it might take for a package bid to be acceptable: the linear price information is unambiguous. As the rounds proceed and the clock prices tick upward, a bidder can peruse the new clock prices and submit any new vector of package bids and constraints (unconstrained by previous round’s bids) along with stating which of his old rounds’ bids he wishes to keep active in the system at their former clock prices. The auction process continues until round r , when there is no explicit excess demand for any resource being offered (${}^r q_i \leq b_i, \forall i$). The clock auction now enters its close-out phase.

If in round r the explicit demand at the current clock prices exactly equals the supply of all resources (${}^r q_i \leq b_i, \forall i$), then the auction has drawn to a successful conclusion, and all resources are awarded at the current clock prices without ever having to solve the winner-determination problem. If at least one of the resources is undersubscribed at the final prices ($\exists i \text{ } {}^r q_i < b_i$), then a winner-determination algorithm must be conducted using all of the nondominated bids intentionally left by bidders in the system up to round r to generate the revenue maximizing allocation ${}^r(Z^*, x^*)$. If this solution to the winner-determination algorithm discards any package j (i.e., ${}^r x_j^* = 0$), which was a standing package at the round r prices, then there is implicit competition for the resources in the discarded package and the price of at least one of those resources in that package

must be increased. For example, suppose that we have three single items for sale (A, B, and C) and three bidders: the first wants to win

only package AB, the second only package BC, and the third only wants item A. The bidding proceeds as indicated:

Round	Item Prices			Package Bids Submitted			Aggregate Item Demands		
	A	B	C	{AB}	{BC}	{A}	A	B	C
1	100	100	100	✓	✓	✓	2	2	1
2	120	120	100	✓		✓	2	1	0
3	140	120	100	✓			1	1	0
4	160	140	100				0	0	0

Notice in round three there is only one standing bid remaining, {AB} at a total price of 260, but because there are previous bids, {BC} at 200 from round 1 and {A} at 120 from round 2, that can be combined for more revenue to displace the standing {AB} bid, the auctioneer raises the prices on items A and B because of the implicit competition. Notice in round four {AB} quits and {BC} and {A} would be declared the auction winners.

In fact, there may be more than one standing package discarded and more than one resource i , which requires price increases during the close-out phase. The center sets $v_i^{r+1} \leftarrow v_i + \epsilon_i$ for all resources i , for which there is implicit competition, and the auction process continues to the next round $r + 1$. Bidders are again asked to respond to the new prices just as in previous rounds. From the bidder's perspective, it is impossible to tell whether the center is in the close-out phase or not! This process continues until no standing package bids are discarded in the latest winner determination. The final allocation always includes all standing bids at the final clock prices, but may also include old bids from previous rounds that fill demand gaps. Bids from previous rounds that make into the final allocation are charged at the prices from the round from which they were retrieved. This means that prices are non-linear in nature. The final clock prices are akin to the D_R prices in RSB, at which price level no package is rejected. The packages retrieved from previous rounds are akin to those sold exactly at their bid prices below the D_R but above the D_A prices in RSB.

Notice that while the computational burden of the auction has been reduced significantly during the process, there remains the possibility of being required to solve sequentially for winner determination during the close-out phase. However, by the time the close-out phase arrives, much preprocessing can be accomplished by the center to help prune the decision tree and reduce the computational burden of winner determination. Constraints placed on each rounds' package bids, including budget constraints across bids, are considered only when solving for winner determination during the close-out phase.

The simple and natural price discovery format, maintained privacy with regard to each bidder's maximal willingness to pay, and the fact that no demand information is passed on to auction participants (including when the close-out phase is executing) are the apparent keys to the success of PRRS auction.

Another variant of the combinatorial clock auction, the clock-proxy auction, has been proposed by Ausubel, Cramton, and Milgrom (ACM) [20]. This auction has a second stage (in addition to an initial clock phase), in which mutually exclusive package bids from each bidder is submitted through a proxy agent preinformed by the bidder concerning the maximum that it should bid for each package. The clock phase of ACM has several differences from PRRS: agents are privy to excess demand information; price increments are calculated in a predetermined linear manner; there is no close-out phase to resolve implicit demand amongst old bids

for unallocated resources; and there is an activity rule which regulates what you can bid on in any later round given what you bid on in previous rounds. ACM claim that without an activity rule strategic insincere bidding will plague a clock auction; however, PRRS report its clock auction performs well without an activity rule given that bidders are not privy to the demand in the system at any point during the auction and they are uncertain concerning how the close-out phase will play out (whose bids will be retrieved).

The proxy stage of the Clock-Proxy auction is similar to holding a sealed-bid auction after the initial clock auction stage, with all clock stage bids remaining binding. In our previous discussion of the Vickrey auction and its failures, we spent no time discussing issues of implicit collusion by bidders. ACM concludes that a clock auction by itself would do well in certain competitive environments, but that the proxy phase helps prevent tacit collusion in the form of premature demand reduction during their clock stage. However three features of PRRS, a pure clock auction, should make it difficult for bidders to tacitly collude

- no public provision of demand information (who's in for which items at each round);
- no explicit price increment rules need to be provided (increments are the auctioneer's prerogative);
- no indication of having reached the close-out phase (at any round competition for items might be explicit due to excess demand from current bidders or implicit due to former bidders displacing current bidders).

Whether the ACM and PRRS auctions are broadly robust against tacitly collusive activity remains to be thoroughly tested.

Some Design Detail Issues

1. *Computation.* We have discussed the 2^N bogeyman associated with the winner-determination problem. This issue has sparked many papers intended on solving this problem. Some

papers have discussed limiting the type/set of bids that can be submitted so that the computation becomes relatively straight-forward [20,21]. Others have devised clever algorithms (including "simple" greedy methods) to lessen the computational issues for large problems (see Sandholm [22] for a review of these). Lastly, some researchers are examining noncomputational methods to reduce the computational burden [23].

2. *Speed.* The clock auctions of PRRS and ACM are both dependent upon choosing parameters that determine the speed of price changes as the auction progresses. Clearly, if the price increments are larger the auction moves faster, but there is a danger of overshooting the limit prices of bidders and reducing the efficiency of the resulting allocation. The relationship between overaggressive price augmentation and allocative inefficiency is not well studied. PRRS offers little guidance to choosing optimal price increments, but indicates that high levels of efficiency can be achieved without much concern in the 10 bidder/10 resource environments tested. ACM discusses one method for addressing sudden package withdrawals due to gross changes in price by allowing bidders to submit intra-round bids indicating intermediate limit price withdrawal points, but this process can become cumbersome in environments where there are a large number of resources to be allocated. For the purpose of improving actual field implementations, research in this area would probably be most valuable. It is likely that in addition to the version of the clock auction being implemented, the structural features of the delivered bids should be taken into account in optimally determining price increments.

COMBINATORIAL TRAVELING SALESMAN PROBLEM ALGORITHMS

CLAUDIA D'AMBROSIO
ANDREA LODI
SILVANO MARTELLO
DEIS, Università di Bologna,
Bologna, Italy

INTRODUCTION AND NOTATION

Given a set of cities, and the cost of traveling between each pair of them, the *traveling salesman problem* (TSP), calls for finding a unique tour visiting all cities at minimum cost. Besides being for sure the best known combinatorial optimization problem, the TSP has many applications, not only in operations research/management science (especially in transportation and logistics), but also in many other fields, such as genome sequencing or drilling of printed circuits boards. In fact, there are no fewer than four books devoted to it, see Lawler *et al.* [1], Reinelt [2], Gutin and Punnen [3], and Applegate *et al.* [4].

Throughout this article, we distinguish between the *symmetric* TSP (STSP), in which the cost of traveling from city A to city B is the same as the cost of traveling in the reverse direction, and the *asymmetric* TSP (ATSP), in which these costs are permitted to be different. The former version can be modeled by a *graph* $G = (V, E)$, where $V = \{1, \dots, n\}$ is a set of *vertices* and E is a set of unordered pairs $[i, j]$ of vertices, called *edges* (with $|E| = m$). The latter version can be modeled by a *digraph* (directed graph) $G = (V, A)$, where A is a set of ordered pairs (i, j) of vertices, called *arcs* (with $|A| = m$).

All graphs and digraphs considered in this article are *simple*, that is, they have no loops and no two of their edges or arcs connect the same pair of vertices (in the same direction, in the case of digraphs).

The *cost* of traveling along edge $e = [i, j]$ (in either direction), or along arc $a = (i, j)$ (from i to j), will be denoted by c_{ij} , or, alternatively, by c_e and c_a , respectively. For a graph $G = (V, E)$, we will denote by $\delta(v)$ ($v \in V$) the set of edges having v as one end vertex. For a digraph $G = (V, A)$, we will denote by $\delta^+(v)$ (and $\delta^-(v)$, respectively) the set of arcs leaving (and entering, respectively) vertex v .

The TSP is $\mathcal{NP}$ -hard in the strong sense, and very difficult to solve in practice. Nevertheless, and surprisingly, large-scale instances arising in practice can often be solved to proven optimality (or near-optimality) by modern solvers. Currently, the most successful technique is the so-called *branch-and-cut* (see **Branch and Cut**), a general technique based on the solution of the linear programming (LP) relaxation, which was indeed developed in the context of the TSP [5,6] (see also **Mathematical Programming Approaches to the Traveling Salesman Problem**).

There are, however, a number of solution approaches alternative to branch-and-cut, most of which are based on graph-theoretic relaxations rather than linear programming. We refer to such approaches as *combinatorial* TSP algorithms. They are relevant both from theoretical and historical points of view, and because they are competitive for the solution of the ATSP.

In the next section, we review some of the TSP ancestors, including the famous Hamiltonian cycle problem (HC), of which the TSP is the weighted version. In the section titled "Formulations," we review the most famous formulations for both symmetric and asymmetric TSP. Then, we consider in the section titled "Algorithms for the Symmetric TSP" combinatorial approaches for the symmetric TSP, whereas the algorithms for the asymmetric TSP are presented in the section titled "Algorithms for the Asymmetric TSP." Finally, in the section titled "Software," we briefly discuss the availability of TSP software and we give some useful pointers.

THE ORIGINS AND THE HAMILTONIAN CYCLE PROBLEM

The origins of the TSP date back to the eighteenth century, when Leonard Euler studied the *knight's tour problem*: a knight is placed on an empty $n \times n$ chessboard and must visit each square exactly once by only using valid chess moves of a knight. The tour is called *closed* if the knight ends on a square from which there is a legal move to the starting square, or *open* otherwise. In a study presented in 1759 (but published only 7 years later), Euler [7] proposed a number of possible solutions to the problem for the classical case $n = 8$.

By defining a graph in which the vertices correspond to the chessboard squares and the edges to the legal knight moves, an open (and closed, respectively) knight's tour corresponds to a path (and a cycle, respectively) that visits every vertex of the graph exactly once. Such paths and cycles are called *Hamiltonian* in honor of Sir William Rowan Hamilton, a great Irish mathematician of the nineteenth century, famous for the invention of hypercomplex numbers known as *quaternions*.

In 1859, Hamilton invented a game that was played on a wooden planar representation of the edges of a dodecahedron, with holes at each of the 20 vertices: The first player stuck 5 pegs in any consecutive vertices, and the second player was requested to stick the remaining 15 pegs so as to complete the resulting path to a cycle visiting each vertex exactly once. The idea of the game, called the *Icosian game*, was sold for £25 to a Dublin toy manufacturer. (It seems that the sales were not satisfactory though.) Many details on the life and achievements of Hamilton can be found in the page maintained by the Hamilton Mathematics Institute, Trinity College Dublin at <http://www.hamilton.tcd.ie/>.

The problem of deciding if a graph or a digraph possesses a cycle that passes through all vertices exactly once is thus known as the Hamiltonian Cycle problem. It is a generalization of the knight's tour problem discussed above, and the special case of the TSP that arises when all edges of E , or all arcs of A ,

have unit cost (while infinite cost is assumed for traveling between vertices not connected by an edge or arc). The HC is one of the first problems proved to be $\mathcal{NP}$ -complete: its two versions (for graphs and digraphs) appear indeed in the list of 21 problems for which Karp [8] proved $\mathcal{NP}$ -completeness in his famous 1972 paper. In the second half of the twentieth century, an impressive amount of results has been produced on this problem.

An important stream of research consists in finding conditions ensuring that if a graph has a sufficient number of edges then it is *Hamiltonian*, that is, it possesses at least one HC. All results below refer to graphs in which the number n of vertices is at least 3. The first seminal result was obtained by G.A. Dirac [9] in 1952, and reads

A graph $G = (V, E)$ such that $|\delta(i)| \geq n/2$ for every $i \in V$ is Hamiltonian.

The result was strengthened by Ore [10] in 1960:

A graph $G = (V, E)$ such that $|\delta(i)| + |\delta(j)| \geq n$ for every pair of nonadjacent vertices $i, j \in V$ is Hamiltonian.

(Analogous results hold for the case of digraphs, see Ghouila-Houri [11] and Meyniel [12].) This flood of research culminated in the necessary and sufficient conditions established in 1976 by Bondy and Chvátal [13]. They first observed that the proofs of the results by Dirac and Ore imply the following one:

Given a graph $G = (V, E)$, let i and j be two nonadjacent vertices of V such that $|\delta(i)| + |\delta(j)| \geq n$. Then G is Hamiltonian if and only if $G' = (V, E \cup \{i, j\})$ is Hamiltonian.

Now, define the *closure* of $G = (V, E)$ as the graph obtained from G by recursively adding to E edges $[i, j]$ connecting pairs of nonadjacent vertices i, j such that $|\delta(i)| + |\delta(j)| \geq n$ until no such pair remains. Then, we have the Bondy–Chvátal theorem:

A graph $G = (V, E)$ is Hamiltonian if and only if its closure is Hamiltonian.

Following the above results an impressive number of extensions and refinements has been developed. The reader is referred to the surveys by Bermond [14] and Gould [15,16] for thorough reviews.

Another relevant stream of research consists in developing exact and heuristic algorithms to find HCs in a graph or a digraph. Most of these algorithms (of both kinds) are based on the enumeration method developed in 1966 by Roberts and Flores [17]. We describe it for a graph, the adaptation to digraphs being straightforward. The general strategy is to progressively extend a simple path, going, say, from vertex s to vertex t , by adding at each iteration a feasible edge $[t, k]$, where feasible means that vertex k is not already in the path. The extension continues until either

1. the path includes n vertices, that is, it is Hamiltonian; or
2. no feasible edge exists.

In the former case, if $[t, s] \in E$ we have obtained a HC. Otherwise, and in case (2), exact algorithms backtrack in a systematic way so as to ensure that at the end all possibilities have been explored, while heuristic algorithms modify the current path so that new edges can hopefully be added.

A number of exact algorithms have been developed by improving the above basic enumeration method [18–21]. The improvements are essentially based on (i) identifying edges which cannot be part of any HC, and deleting them from the current graph; (ii) identifying edges which must be in any HC (forced edges), and including them in the current partial solution. Forced edges can in turn produce forced paths, which can lead to further additions and deletions (*multipath* methods). Concerning heuristic algorithms [22–25], most techniques for modifying a path that cannot be extended any longer are based on the following idea by Pósa [26], known as *rotation* (not adaptable to digraphs). Given the current path $(i_1, i_2, \dots, i_\ell, i_{\ell+1}, \dots, i_k)$ and an (infeasible) edge $[i_k, i_\ell]$, create a new path of the same length by deleting edge $i_\ell, i_{\ell+1}$,

and inserting edge $[i_k, i_\ell]$: the new path is $(i_1, i_2, \dots, i_\ell, i_k, i_{k-1}, \dots, i_{\ell+1})$.

A review of exact and heuristic algorithms has been given by Vandegriend [27]. The HC area includes many other streams of research. The surveys cited above discuss hundreds of results in this exciting field.

FORMULATIONS

The most well-known and used formulation of the TSP was introduced in the seminal paper by Dantzig *et al.* [28]. Given a graph $G = (V, E)$ and a subset $S \subset V$, let $\delta(S)$ denote the set of edges with exactly one end vertex in S . For each edge $e \in E$, define a binary variable x_e , taking the value 1 if and only if edge e is in the tour. The STSP is then equivalent to the following 0–1 LP:

$$\min \sum_{e \in E} c_e x_e \quad (1)$$

$$\text{s.t. } \sum_{e \in \delta(i)} x_e = 2 \quad (\forall i \in V), \quad (2)$$

$$\sum_{e \in \delta(S)} x_e \geq 2 \quad (\forall S \subset V : 2 \leq |S| \leq |V| - 2), \quad (3)$$

$$x_e \in \{0, 1\} \quad (\forall e \in E). \quad (4)$$

Equations (2), called *degree equations*, express the fact that the salesman must arrive at and depart from each city. Inequalities (3), called *subtour elimination constraints* (SECs), ensure that the tour is connected.

The ATSP can be formulated in a very similar way using a digraph $G = (V, A)$. For any subset $S \subset V$, let $\delta^+(S)$ denote the set of arcs leaving S . For each arc $(i, j) \in A$, define a binary variable x_{ij} taking the value 1 if and only if arc (i, j) is in the tour. The ATSP is then equivalent to the following 0–1 LP:

$$\min \sum_{(i,j) \in A} c_{ij} x_{ij} \quad (5)$$

$$\text{s.t. } \sum_{j \in \delta^+(i)} x_{ij} = 1 \quad (\forall i \in V), \quad (6)$$

$$\sum_{i \in \delta^-(j)} x_{ij} = 1 \quad (\forall j \in V), \quad (7)$$

$$\sum_{(i,j) \in \delta^+(S)} x_{ij} \geq 1$$

$$(\forall S \subset V : 2 \leq |S| \leq |V| - 2), \quad (8)$$

$$x_{ij} \in \{0, 1\} \quad (\forall (i, j) \in A). \quad (9)$$

Equations (6) and (7) are called *out-degree* and *in-degree* equations, respectively, while inequalities (8) are again called SECs.

Even if, in both formulations, the SECs are exponential in number, this is not a dramatic issue for enumeration algorithms that can generate them *on the fly*, by using polynomial-time separation procedures (see **Branch and Cut**). However, alternative formulations involving a polynomial number of constraints exist and are discussed in the survey by Öncan *et al.* [29].

ALGORITHMS FOR THE SYMMETRIC TSP

For the STSP, the exact algorithms based on the iterative solution of the linear programming relaxation of model (1)–(4) have been proven to be, by far, the most successful approaches. Such algorithms are described in details in the article titled **Mathematical Programming Approaches to the Traveling Salesman Problem** in this encyclopedia. The current section covers the *combinatorial* algorithms that represent milestones for the resolution of the symmetric TSP including some heuristic approaches.

In 1962, Bellman [30], Gonzales [31], and Held and Karp [32] proposed *dynamic programming* based algorithms specialized for symmetric TSPs. The basic idea is that it is possible to build the optimal solution step by step. At iteration k , all subsets S of cities with cardinality k (not containing vertex 1) are considered, and all paths starting from vertex 1 and ending at each vertex of S are computed. The paths of minimum cost are stored. At iteration $k + 1$, the new minimum-cost paths are obtained from those of the previous iteration. The optimal tour is finally constructed from the minimum-cost paths of subset $V \setminus \{1\}$, by connecting the last visited vertex to vertex 1, and taking the minimum-cost tour. The theoretical time bound of this

kind of algorithms was determined by Held and Karp [32]: an instance of n cities can be solved in time at most proportional to $n^2 2^n$. Although such complexity is nonpolynomial, it compares favorably with that of the complete enumeration of all Hamiltonian circuits, which takes time proportional to $(n - 1)!$. Unfortunately, in practice dynamic programming can only be used to solve small size instances, due to the amount of data which must be stored and examined, proportional to $n 2^n$.

An important role in the resolution of the symmetric TSP has been played by branch-and-bound algorithms (see **Branch-and-Bound Algorithms**). In 1963, Little *et al.* [33] developed the first complete branch-and-bound algorithm for the TSP (and actually were the first to propose such a name) by specializing the framework of Land and Doig [34]. Several earlier enumeration algorithms for the TSP were presented before 1963, the most notable being the one by Eastman [35], whose algorithm can probably fit into the branch-and-bound framework. Little *et al.* [33] based their branch-and-bound approach on the LP relaxation. In particular, the lower bound on the TSP cost is computed by finding an approximate dual solution, that is, a lower bound on the LP relaxation of the problem.

The most famous lower bound, which represented a breakthrough in the study of the TSP, was proposed by Held and Karp [36,37]. Remind that a shortest spanning tree of a graph $G = (V, E)$, with $n = |V|$, is a minimum-cost subset of $n - 1$ edges of E that spans all vertices of V (see **Minimum Spanning Trees**). The peculiarity of the branch-and-bound algorithm by Held and Karp is the use of a lower bound given by the shortest spanning tree of the subgraph of G which does not include vertex 1, plus the two minimum-cost edges connecting vertex 1 to the other vertices. (This particular structure is called *1-tree*.) The advantages of such a lower bound are basically two: the shortest spanning tree can be found in $O(n^2)$ time, and the resulting lower bound turns out to be generally good. The bound is tightened through a technique based on a result by Flood [38]. Suppose that we associate a value λ_i to each vertex $i \in V$,

and modify the cost of each edge $e = [i, j]$ as $c_{ij} := c_{ij} - \lambda_i - \lambda_j$. In every tour, each vertex has exactly two incident edges, hence its cost changes by $\sum_{k \in V} 2\lambda_k$. It follows that the optimal tour remains optimal, while the optimal 1-tree generally changes since in a 1-tree the vertices have different degrees. In order to choose the λ values that provide the tightest 1-tree lower bound, Held and Karp developed an iterative technique which, at each iteration, increases (respectively decreases) λ_k ($k \in V$) if, in the current 1-tree, vertex k has one incident edge (respectively more than two incident edges). This technique is related to the Lagrangean relaxation of the degree constraints (2) and the determination of the corresponding Lagrangean multipliers through a subgradient optimization procedure. The reader is referred to Refs [36,37] and to Chapter 4 of Applegate *et al.* [4] for details.

While the 1-tree lower bound is obtained by relaxing constraints (2), another important lower bound comes from the relaxation of constraints (3). The resulting problem is to find, in general, a set of minimum-cost disjoint tours covering all vertices, and is known as *perfect 2-matching*. Such a problem is solvable in polynomial time [39]. The resulting bound is generally not very tight, although techniques for improving it exist. Other lower bounds for the STSP have been obtained by Houck *et al.* [40] (*n-path relaxation*) and by Cowling and Maffioli [41] (*matroid relaxation*).

Among the heuristic algorithms for the TSP, the most successful is probably the local search procedure proposed in 1973 by Lin and Kernighan [42]. They extended an idea by Flood [38], who had proposed the so-called *2-opt move*: starting from a given tour including edges $[i, j]$ and $[k, l]$ (assume that the vertices are in the same order of visit), it is convenient to replace them by edges $[i, k]$ and $[j, l]$ if $c_{ik} + c_{jl} < c_{ij} + c_{kl}$. Lin and Kernighan generalized the *2-opt move* to the more complex *k-opt move* where k edges are replaced with respect to the initial solution. Considering $k > 3$ is impractical in general, but the key-point of Lin–Kernighan’s heuristic is to avoid fixing k to a prefixed value while instead looking for special *k-opt moves*,

with large k , obtained by carefully selected sequences of *2-opt moves*. The quality of the tours obtained in this way is high, and the Lin–Kernighan algorithm is nowadays employed in most exact algorithms for the TSP, usually in the improved version proposed by Helsgaun [43].

Finally, it is worth presenting a fundamental result by Christofides [44] who, in 1976, proposed a polynomial-time algorithm that provides a tour of cost not greater than $3/2$ times the cost of the optimal one for the metric TSP. A TSP instance is *metric* if, for any $i, j, k \in V$, $c_{ij} \leq c_{ik} + c_{kj}$ (*triangle inequality*) holds. The Christofides algorithm starts by finding the shortest spanning tree T of graph G , and the minimum-cost perfect matching M in the subgraph induced by the vertices of odd degree in T . (A *matching* is a subset of edges with no vertex in common, and it is *perfect* if every vertex is an end point of one edge of the matching.) It then forms an Eulerian path (i.e., a path that uses each edge of the graph exactly once) in the multi-graph produced by all edges of T and M , and shortcuts it by skipping repeated vertices: if edges $[i, k]$ and $[k, j]$ are in the path, and k has already been visited, they are replaced by edge $[i, j]$.

This simple and elegant algorithm still provides the tightest approximation guarantee for the metric TSP.

ALGORITHMS FOR THE ASYMMETRIC TSP

In the asymmetric case, there is no dominance between mathematical programming based algorithms and combinatorial branch-and-bound approaches. In particular, the branch-and-cut approach by Fischetti and Toth [45,46] (see **Branch and Cut** for details on branch-and-cut algorithms, and **Mathematical Programming Approaches to the Traveling Salesman Problem** for the specific branch-and-cut for the ATSP) is the fastest algorithm on the asymmetric instances of the TSPLIB [47,48]. However, if the instances are randomly generated in such a way that the costs c_{ij} and c_{ji} for each pair $i, j \in V$ are uncorrelated, then combinatorial algorithms become competitive

and sometimes outperform branch-and-cut approaches (mainly because they are simpler). Note that uncorrelated instances are not necessarily artificial: they do appear in real-world applications like the stacker crane problems described by Ascheuer [49].

Combinatorial algorithms for the exact solution of the ATSP are based on two well-known relaxations. The first one is the *linear assignment problem* (AP) relaxation, obtained by dropping SECs Eq.(8) from models (5)–(9). The surviving constraints impose that each vertex has exactly one leaving arc and one entering arc. Thus the AP is the graph-theoretic problem of finding the minimum-cost collection of vertex-disjoint subtours visiting all vertices of a digraph $G = (V, A)$. The AP can be solved in $O(n^3)$ time (see the recent book by Burkard *et al.* [50] for a thorough analysis of AP algorithms).

The second important relaxation is the *Spanning r -Arborescence Problem* (r -SAP), obtained by dropping constraints (6) from model (5)–(9). Such a problem corresponds to finding a minimum-cost spanning subdigraph $\bar{G} = (V, \bar{A})$ of G such that: (i) the in-degree of each vertex is exactly one; and (ii) each vertex can be reached from a given root vertex r . Such a relaxation can be solved in $O(n^2)$ time by adding a minimum-cost arc entering vertex r to the *shortest spanning arborescence rooted at r* , that is, to the same sub-digraph but with zero in-degree at the root r (see *Minimum Spanning Trees*).

Note that for both the AP and the r -SAP relaxation one can drop the integrality requirements (9) as their linear relaxation always possesses an integer optimal solution which is easily found by the combinatorial algorithms.

It is not difficult to see how one can build a naïve branch-and-bound algorithm by repeatedly solving either AP or r -SAP relaxations. It is less obvious how to make such algorithm effective in practice, and how to combine the two relaxations into a unique algorithm. These two issues are discussed below.

All the effective AP-based branch-and-bound algorithms are derived from the lowest-first branch-and-bound procedure TSP1 presented by Carpaneto and Toth [51].

At each node h of the decision tree, procedure TSP1 solves a *modified* AP (MAP_h) which is the AP plus the additional variable-fixing constraints associated with the arc subsets of *excluded* and *forced* arcs. Thus, MAP_h can easily be transformed into a standard AP by properly modifying the cost matrix so as to take care of the additional constraints.

If the optimal solution to MAP_h does not define a Hamiltonian directed cycle, then ℓ children nodes are generated from node h according to a modified version of the classical subtour elimination rule by Bellmore and Malone [52], where ℓ is the length of the smallest subtour associated with the MAP_h solution. Precisely, if $a_1, \dots, a_\ell$ are the not fixed arcs of such a subtour, the ℓ nodes are generated as

$$x_{a_1} = 1 \vee (x_{a_2} = 1 \wedge x_{a_1} = 0) \vee \dots \vee (x_{a_\ell} = 1 \wedge x_{a_1} = \dots = x_{a_{\ell-1}} = 0). \quad (10)$$

Based on the above branch-and-bound scheme, two very effective AP-based algorithms have been proposed by Miller and Pekny [53], and Carpaneto *et al.* [54]. Both algorithms include a number of sophisticated techniques aimed, among other issues, at reducing the size of the graph and at finding good heuristic solutions. However, the main improvement is the parametric solution of each MAP_h in $O(n^2)$ time, which speeds up the overall computation significantly. On the whole, the two methods exhibit a comparable performance.

Coming to the combination of the AP and r -SAP relaxations, preliminarily observe that such relaxations are complementary to each other. Indeed, the AP imposes the degree constraints for all vertices, disregarding connectivity constraints, while r -SAP imposes reachability from vertex r to all other vertices, disregarding out-degree constraints for all vertices.

A possible way of combining the two relaxations is to apply the so-called *additive approach* that Fischetti and Toth [55] related to the restricted Lagrangean relaxation approach by Balas and Christofides [56], and later used for the ATSP [57]. Roughly speaking, given a set of bounding procedures for a problem P , one can apply them in

sequence so that the reduced costs output by a procedure are used as an input for the next one. Then, the sum of the solution values of all the procedures is a valid bound for P .

In the specific ATSP case, the AP relaxation is solved first, and the resulting reduced cost matrix defines a new ATSP instance on which the r -SAP is solved. The sum of the values of the optimal solutions of the two relaxations is a valid lower bound for the ATSP.

Finally observe that a third relaxation can be easily defined and used in such a framework, namely the *Spanning r -Antiarborescence Problem* (r -SAAP), which is the same as the r -SAP but with the in-degree constraints (7) dropped instead of the out-degree constraints (6).

We conclude this section with some considerations on the approximation of the ATSP. The existence of a polynomial-time algorithm with worst-case error bounded by a constant is still an open question. The most famous result in this field was obtained by Frieze *et al.* [58], whose polynomial-time algorithm, based on the iterated solution of AP relaxations, provides, for the metric ATSP, a solution with performance guarantee $\log n$. This bound was not improved until 2002. Recently Asadpour *et al.* [59] presented a randomized algorithm that produces a solution within a factor of $O(\log n / \log \log n)$ of the optimum with high probability.

SOFTWARE

As already discussed, the TSP has attracted over the years the attention of a number of researchers and practitioners, often belonging to different communities. As an effect almost all algorithmic techniques, both exact and heuristic, have been tested on the TSP. Often, the codes associated with such algorithms have been made available for research and teaching. The purpose of such software might be very different. There are applications (especially Java) created with didactic purposes, or implementations intended as examples for the use of a special algorithmic environment, or pieces of code available as building blocks for more complex software projects. Of course, exhibiting the fastest

computer code to solve the TSP is always a great motivation and this is the case of Concorde [60] by Applegate *et al.* [4].

Many TSP software codes are classified in Lodi and Punnen [61] and the associated web page—http://www.or.deis.unibo.it/research_pages/tspsoft.html—is continuously maintained.

INTRODUCTION

The combination of exact and heuristic methods is as old as mathematical programming (MP) itself, because usually exact methods cannot work properly without a good bound on the optimal cost, which helps prune the search space. However, it is only in very recent years that the combination has also gone the other way round, permitting the use of methods originally conceived for exact problem solution also in heuristic frameworks. Noteworthy exceptions have existed, but mainstream approaches in heuristic and metaheuristic researches have traditionally been quite oblivious to elements like bounds, duality, pruning, cutting planes, column generation, and in general of all the armamentaria that makes effective exact codes. This reflected on the scarce attention given to such topics in most conferences and publication outlets dedicated to heuristics or metaheuristics.

This state of things has changed, mainly because of the steady performance improvement of mixed-integer programming (MIP) solvers. The current effectiveness of MIP solvers—mainly of the commercial ones, but some open source ones are becoming an option, too—makes it viable to use them as subroutines for solving (NP-hard) subproblems arising during heuristic search.

MIP solvers used as subroutines are not the only option for designing exact/heuristic hybrids. In this article, we are particularly

interested in revising the newly identified field of *matheuristics*, which refers in particular to algorithms combining metaheuristics with model grounded, typically MIP, techniques. This choice was made because the coverage of the different ways in which generic heuristics have been used as subroutines inside exact codes would imply, as mentioned, a review of 50 years of research in MP. The same is true when considering how exact codes can be turned into heuristics, since every exact code is a heuristic when run under time or memory constraints. Considering metaheuristics alone, it permits to focus on a wide and well-defined research community, which self-statingly produces the best performing generic algorithms for the real-world, NP-hard combinatorial optimization (CO) problems. Besides the fact that for most CO problems they are the method that produced the best known results in the literature, acknowledged merits of metaheuristics also include the fact that they are usually easy to adapt to the many variants of any given problem and that they are usually also easy to design and implement, given a problem.

Moreover, the set of algorithms, which are classified as metaheuristics has significantly enlarged in recent years. Therefore, despite its novelty, to this date more than 50 research papers have already been published under the *matheuristics* heading, journal special issues and book edited collections are in print, and a dedicated international workshop series exists, besides several special sessions on broad coverage optimization conferences. A first analysis of the state of the art can thus be of interest.

Contributions to this area can be classified into two main groups, “how can metaheuristics help exact methods” and “how can exact methods help metaheuristics.” This last contains contributions consisting either of a driving exact approach used to define new metaheuristic techniques, or of a driving metaheuristic algorithm using an exact code as a subroutine. Following either of

these approaches, it has been shown how metaheuristics and MP can leverage on one another, permitting to improve the state of the art on several problems of theoretical interest or arising from real-world practice.

This article reflects this classification, consisting of three sections, the section titled “introduction,” the section titled “MP for Metaheuristics” on metaheuristics using MP as a subroutine, and the section titled “Metaheuristics for MP” on metaheuristics used by MP as a subroutine. The constraint on the length of this article rules out the possibility of an in-depth analysis of the different contributions. Relevant collections can be found in Refs 1–5, while Caserta and Voß [6] provide a detailed overview, which helps to frame the metaheuristics contributions in the more general context of metaheuristics advances. Throughout the text, unless otherwise specified, we make reference to minimization problems, therefore upper bounds are cost of feasible solutions and lower bounds are possibly better-than-optimal costs.

One area of contribution, which escapes this taxonomy refers to the use of mathematical tools to model and predict the performance of metaheuristic. It does not directly refer to hybrid solution techniques, but we like to mention it here because of the complexity and of the quality of the contributions. For example, Gutjahr [7] gives an overview on techniques for proving convergence of metaheuristics to optimal or sufficiently good solutions and estimation of expected runtime, that is, of the time needed by a metaheuristic to hit for the first time, a solution of a required quality. This can be done for metaheuristics applied both to deterministic and to stochastic CO problems. For related research, see also Refs 8–13.

MP FOR METAHEURISTICS

This is the area most intensively studied, where the potential benefits with respect to the state of the art seem to be more immediate. We can identify two directions along

which research is developing. The first makes use of MP results—mainly MIP solvers—as components to be included in an existing metaheuristic framework, such as tabu search, genetic algorithms (GAs), or ant colony optimization (ACO). The second direction aims at producing new metaheuristic frameworks, directly derived from the internal workings of MP methods.

MP as a Subroutine for Known Metaheuristics

This approach is the one that directly makes most use of the complementary merits of MP and metaheuristic algorithms. Most best-known metaheuristic frameworks have been by now complemented in some of their internal steps by MP codes. This is true from hybrids of local search variants and MP techniques, for which an interesting review can be found in Refs 14 and 15, up to hybrids of the most involved frameworks, such as ACO or particle swarm optimization (PSO).

One of the first investigated areas has been the exact recombination of parents, in the frameworks of GAs or alike (evolution strategies, scatter search, memetic algorithms, etc.). The topic of finding the best possible offspring, as a result of a recombination operator in an evolutionary algorithm (EA), given two parent solutions using binary encoding, is theoretically investigated in Ref. 16, where some cases of polynomial or NP-hard cases for optimal recombination are outlined. Two general approaches are feasible: fixing the solution parts common to both parents and optimizing the rest (see Ref. 17 for an early example) or making the union of the parent solution components and optimizing within that set [18,19].

Liberti *et al.* [20] combine several well-known metaheuristics, namely, variable neighborhood search (VNS), local branching, with sequential quadratic programming and branch-and-bound to obtain a method, called *Relaxed-Exact Continuous-Integer Problem Exploration* (RECIPE), which is applied to general mixed integer nonlinear programming, without hand-tuned parameter configuration.

VNS has been hybridized with MP methods in different ways. In Ref. 21, a

VNS approach is presented, which uses three different neighborhood types. Two of them work in complementary ways in order to maximize search effectiveness. Both are large in the sense that they contain exponentially many candidate solutions, but efficient polynomial-time algorithms are used to identify the best neighbors. For the third neighborhood type, mixed integer programming is applied to optimize local parts within candidate solution trees, considering the generalized version of the classical minimum spanning tree problem where the nodes of a graph are partitioned into clusters; and exactly one node from each cluster must be connected. A different hybridization, this time with local branching, is described in Ref. 22.

ACO took advantage of MP results in different ways. In an approach, named *approximate nondeterministic tree search* (ANTS), [23], lower bounds are used to assess the likelihood of success of the possible ants moves, thus making the overall process quite similar to branch and bound constructions. Another approach, which seems particularly suited for strongly constrained problems, hybridizes ACO functioning with bounded enumeration, or beam-search, expansions [24,25,62]. Here the idea is to expand, at each step, not a single solution but a number of them, retaining for further expansion only the best ones, as determined by lower bound and ants-specific considerations.

GRASP and GA were both integrated with MIP solving by Dolgui *et al.* [26], in the context of a successful application to the problem of balancing transfer lines with multispindle machines. Specifically, they design a GRASP and a GA, which both use a MIP solver as a subroutine for solving subproblems arising in the search process of the metaheuristics.

Tabu search has been hybridized with MIP in different ways. For example, Ulrich-Ngueveu *et al.* [27] studied the *m*-peripatetic vehicle routing problem (VRP), which is a special VRP asking that each arc is used in the solution at most once for each set of *m* periods considered in the plan. Their approach uses a perfect *b*-matching to define

the candidate sets to be passed to a granular tabu search algorithm.

We finally mention here a possibility that, under different forms, will be present in all three sections in which we have partitioned the review part of this article (i.e., the sections titled “MP as a Subroutine for known Metaheuristics,” “MP as a Paradigm for New Metaheuristics,” and “Metaheuristics for MP”), and that we denote as the *core problem* approach. In its essence, it prescribes to collect possible components of the problem solution and to include them in an MIP formulation, usually as columns of a set-partitioning (SP) formulation, possibly with additional constraints. The resulting restricted MIP formulation is then solved in an exact or heuristic way. The roots of this approach can be found in Ref. 28, but see also Refs 29–32 for extensions. In the context of MP as a subroutine for other metaheuristics, this has been used by running the metaheuristic of interest (a GA in Ref. 33, a tabu search in Ref. 34) and collecting elements of the discovered solutions (VRP routes in Ref. 34, node subsets in Ref. 33). These components are then possibly recombined in the MIP solution as a postprocessing of metaheuristic search.

MP as a Paradigm for New Metaheuristics

The difference between a “new” and a significant improvement of an existing framework can be blurred; here we consider to be “new,” a method which could not exist without the MP contribution. This includes both methods, which are essentially local searches, where the neighborhood is defined according to a suitable MIP problem or method, and methods derived from proper MP techniques.

A clear example of how to exploit MIP in neighborhood definition is given by the very large neighborhood search (VLNS) by Ahuja *et al.* [35,36]. This technique was first presented for partitioning problems, a general class of CO problems, which includes vehicle routing, capacitated minimum spanning tree, generalized assignment, graph partitioning, parallel machine scheduling, and location problems [35]. The general consideration is that local search algorithms produce

better results when they are based on large neighborhoods, but the larger the neighborhood the longer the time to explore it, thus the time for the algorithm to get a local optimum. The idea behind VLNS is to consider very large neighborhoods, even growing exponentially with the problem size, but to avoid their explicit exploration. The method can be applied when it is possible to define the neighborhood exploration, in order to identify the best neighbor of the incumbent solution, as a CO problem itself. In this case, it could be possible to solve it efficiently, thus making it viable for the full exploration of exponential neighborhoods. Very good computational results were presented for the capacitated minimum spanning tree [37].

A similar objective, but pursued with totally different means, is at the heart of Dynasearch [38]. Here, again, the authors want to improve the performance of a local search algorithm by searching an exponential size neighborhood in polynomial time. This is attained by allowing a series of moves to be performed at each of the iterations, using dynamic programming to find the best sequence of simple moves to be performed. A condition to check is that the simple moves to combine are mutually independent, that is, that the overall improvement to the objective function that results from the independent moves is equal to the sum of the improvements from the individual moves. Good results were presented for the total weighted tardiness scheduling problem, the traveling salesman problem, and the linear ordering problem.

Yet another way to explore exponential neighborhoods is local branching [39]. This is a general heuristic method for MIP problems, not restricted to CO ones. The method is based on the use of an MIP formulation P of the problem to solve and to start, as any local search, with a first feasible solution x_h of the problem. Then, at each of the iterations, an MIP problem is solved, asking to identify the best feasible solution for P which differs from x_h in at most k variables, where k is a parameter. This corresponds to solve to optimality a suitable k -opt neighborhood of x_h , and it is achieved by introducing

so-called *local branching* constraints in the original formulation P , then using an MIP solver for determining the new incumbent solution. This technique has recently gained a considerable popularity and it has been integrated in several ways. A recent survey on the use of MIP solvers as subroutines for solving NP-hard subproblems arise while solving more complex problems, can be found in Ref. 40. Several real-world applications of local branching are being published [41,42].

A further variation of the idea of solving to optimality, a neighborhood of the incumbent solution is at the heart of the corridor method [43]. Here, the neighborhood is defined according to the method M , which will be used for exploring it, be it an MIP solver, dynamic programming, or any other technique. The neighborhood is a part of the solution space, which can be effectively explored by employing M and it is implemented by imposing exogenous constraints on the original problem. This defines a “corridor” around an incumbent solution along which the solver is forced to move. An application is presented in Ref. 44 on the blocks relocation problem in block stacking systems, with application in the stacking of container terminals in a yard. The proposed algorithm is based on a dynamic programming formulation, defining a two-dimensional “corridor” around the incumbent blocks configuration.

There are also methods rooted in MP, which depart from the optimized neighborhood search approach. Boschetti *et al.* [45, 46] show how it is possible to use decomposition techniques, which were originally conceived as tools for exact optimization, as metaheuristic frameworks. The general structure of each of the best known decomposition approaches (Lagrangian, Benders and Dantzig-Wolfe) can, in fact, be considered as a general structure for a corresponding metaheuristic. Special attention is given to Lagrangian decomposition, which has a long track record as a basis for heuristics, for which a novel, fully distributed subgradient optimizer is envisioned. Results are presented for a problem arising in P2P network design [the Membership Overlay Problem, (MOP)]

and for a more standard network design problems [61].

Bartolini and Mingozzi [47] propose an algorithm which builds on partial enumeration search. The new algorithm, named *F&B* (shorthand for “Forward and Backward”), escapes from local minima by adopting a memory-based look ahead strategy that exploits the knowledge gained in its past search history. It iterates a partial exploration of the solution space by generating a sequence of enumerative trees of two types, called *forward* and *backward trees*. Each node at level h of the trees represents a partial solution X^L containing h items. At each iteration t , the algorithm generates a forward tree if t is odd, or a backward tree if t is even. In generating a tree, each partial solution X^L is extended to a feasible one using as completion candidates the partial solutions generated at the previous iteration, and stored in the reverse-ordered tree. The cost of the resulting solution is used to guess the quality of the best complete solution that can be obtained from X^L .

Finally, we mention the MP-as-metaheuristic variant of the *core problem* approach introduced in the section “MP as a Subroutine for Known Metaheuristics.” In this case, it consists in working directly on the MIP formulation of the problem of interest trying to iteratively generate as many columns as possible and solving, again in an exact or heuristic way, the resulting MIP instance. This idea was advocated first for solving large set covering instances [48,49], then named *Kernel Search* by Speranza *et al.* [50]. Here, an initial solution is obtained over a small set of promising elements, denoted as the problem *kernel*. The kernel is initially built using information provided by the solution of the linear relaxation of the original problem (for a similar approach, see also Ref. 51). Then new promising elements are identified by solving a sequence of small/moderate size MIP problems, each restricted to the previous kernel plus a set of other elements that were identified by the previous MIP problem in the sequence. An application to portfolio optimization is proposed [50].

METAHEURISTICS FOR MP

This is a relatively unexplored area, where contributions are just starting to be published. Puchinger *et al.* [52] propose a first review of this subject, showing how the possibilities for allowing exact codes to take advantage of metaheuristic computations are varied, and range from providing good quality starting solutions to using metaheuristics for cut separation or column generation.

The most obvious way to use metaheuristics in an exact context is to get tight upper bound to prune the search tree. This can be simply done running a metaheuristic before the exact method, but more elaborate proposals exist. For example, Rothberg [53] integrates an EA in a branch and cut, applying it at regular intervals as tree node heuristic. The population of the EA consists of the best nonidentical solutions found so far, which have either been discovered by the MIP tree search or by previous iterations of the EA itself.

The use of heuristics to separate violated cuts has always been common practice when implementing branch-and-cut methods. Occasionally, metaheuristics were used to this end. A first proposal in this direction was made by Augerat *et al.* [54] in the context of the capacitated VRP. They propose a branch-and-cut algorithm in which a set of methods ranging from simple construction to a tabu search are used for separating capacity constraints. The algorithm starts with the fast simple heuristic and switches to a more complex strategy when no more valid cutting planes could be found. A similar procedure was used by Gruber and Raidl [55], in the context of a branch and cut for the bounded diameter minimum spanning tree problem, based on so-called *jump inequalities*. The separation subproblem of identifying violated jump inequalities is difficult, and was approached by two alternative greedy construction heuristics, followed by local and tabu search to identify and strengthen violated cuts. Moreover, they include in their approach a variable neighborhood descent for finding good primal solutions.

This led to very interesting computational results.

A different possibility was explored by Rei *et al.* [56]. They worked on a Benders decomposition of an MIP problem and suggested to start obtaining different heuristic solutions of the problem to solve (using local branching in their case). These solutions, besides providing good upper bounds, allow to derive multiple additional cuts before solving the Benders master problem.

Another area which calls for profitable use of metaheuristics is the column generation phase (or the pricing problem) in a column generation algorithm. Puchinger and Raidl [57] describe a branch-and-price algorithm for a special case of bin packing problem. The authors propose to approach column generation by applying a sequence of four methods such as a greedy heuristic, an EA, the solving of a restricted, a simpler IP-model of the pricing problem using CPLEX within a given time-limit, and finally the solving of a complete IP-model by CPLEX. This proved computationally good, especially in time-constrained solution of large-scale instances.

Finally, we have here again the possibility of using the “core problem” approach of the section titled “MP for metaheuristics.” In this case, we have a metaheuristic that can be seen as a preprocessing phase for the exact approach, usually a column generation, feeding elements of good solutions and thus triggering a warm start of the column generation phase [58]. Notice that the contribution of the metaheuristic is not restricted to ensuring a good starting upper bound, which is anyway helpful for any exact search, but it is also important for stabilizing dual variables, thus speeding up the overall search. Furthermore, metaheuristics can be used to generate negative reduced cost columns. This is shown, for example, in Refs 59 and 60, where Ref. 59 makes use of a tabu Search, while Ref. 60 propose a GRASP and a GA which are able to generate at each call not just only one column, but a set of columns with negative reduced costs.

CONCLUSIONS

We are witnessing a steady increase of interest on exploiting MP and metaheuristics synergies. The area is still new, and researchers are exploring it along many different directions. Though a few successful approaches have already been established, for example, local branching or VLNS, we can expect to see new ones appearing in the near future, together with the improvements of methods for which we now have the idea and little more than a proof-of-concept.

INTRODUCTION

Several questions can be posed on the usefulness of combining different forecasts. Is it worth combining forecasts? Is it better to combine forecasts or to combine different sources of data sets? Which individual forecasts we should combine in order to achieve better results? How much can one increase the forecasting efficiency by using combining forecasts? For sure, there is no unique answer for all of these questions. The decision is always application dependent. Sometimes the answer might come from the natural constraints of the problem (e.g., when only a fixed data set is available, the combining data sets option is infeasible). Nevertheless, over the years several methods have been proposed for aggregating forecasts. In this article, we present an overview of this general framework, and we try to address questions relevant to the usefulness of combining forecast methodology.

By combining forecasts, we mean all the aggregation methods that aim to produce a better forecast for estimating the value of some random variable or some series of random variables (a stochastic process). Research toward this direction was triggered by the intuitive belief that a combination of many individual forecasts is better than just one. Individual forecasts can be provided by any computational algorithm or might be the result of an expert decision maker. In general, the combined forecast can be expressed as a weighted average of the individual

forecasts. Combining forecasts methodology is about defining the weights so that the prediction accuracy is maximized. Historically, the first modern attempt was made in 1924 when Gordon asked several people to estimate some lifted weights [1]. By averaging the judgment of many judges, she observed that the estimate had higher correlation with the real value. The formal framework of combining forecasts was first presented by Granger and Bates [2]. Since then, there were several research papers that suggested alternative methods for forecast aggregation.

Through the years, with the development of algorithms, there have been many software packages that aim to offer a framework for forecasting to the end user. Many of these software packages incorporate methods for combining forecasting. In the literature, one can find plenty of documentation and comparative studies for such software [3–6].

The rest of the article is organized as follows: first, we present an overview of the most important methods used in the order of ascending complexity (starting from simple linear aggregation methods of averaging and weighted mean, and then describing more involved nonlinear models). In the last section, we cite some computational results and discuss the potential usefulness of combining forecasts.

METHODS

Combining forecasts based on single models can integrate the merits of different single models to enhance the performance. The combining methods can be roughly classified into two groups: “variance-covariance” methods and “regression-based” methods. According to the combining style of single models, there are two kinds of combining forecasts [7]: linear and nonlinear. In this article, we consider the following linear methods: simple combination, discounted mean squared forecast error (MSFE), shrinkage, factor model, and time-varying parameter (TVP) combination forecasts, as well as nonlinear methods based

on expert knowledge, clustering, and fuzzy logic.

The difference among these methods is based on the manner of how the historical information is employed to combine forecasts and the variability of the weight of a particular forecast during that time period.

Linear Methods

The most widely used method for combining forecasts is weighted average of the individual forecasts. It has the following form:

$$f_c = \sum_i \omega_i f_i, \quad \sum_i \omega_i = 1, \quad (1)$$

where f_c is the combined forecast value and f_i are the individual forecasts and ω_i are the weights that correspond to the importance that every individual forecast has.

Simple Combination Forecasts. In the simple combination method, the combined forecast is computed irrespective of the historical performance of the individual forecasts. As mentioned in the introductory part, the first and the most simple way to combine forecasts is to take the average of all the individual f_i s. In this case, ω_i are all equal to $1/N$ (where N is the number of individual forecasts). This is a simple and more secure way to combine forecasts, especially when we do not have any information about which forecast is more accurate. In cases when we are aware that some forecasts have been more accurate (by utilizing previous knowledge), we modify the weights so that greater importance is given to those with higher accuracy.

The second simple combining forecasts method is a very common practical tactic in order to minimize the influence of such outlier forecasts, that is, removing the highest overestimator and the lowest underestimator (this is also known as *trimming*). In this case, if we have N forecasts, the trimmed combined forecast is given by

$$f_c = \sum_{i=2}^{N-1} \omega_i f_i, \quad (2)$$

provided that f_i s are sorted in ascending order. Here, it is worth noting that we do not consider any constraint on signs of the weights on purpose. As mentioned in Ref. 8, combined forecast might have increased performance if some of ω_i are negative. This might be the case when an individual forecast is historically known to give bad predictions.

Discounted MSFE. The discounted MSFE approach computes the weights, which depend inversely on the historical performance of each individual forecast [9]. In this method, a combined forecast is estimated over a time window $[t, t+h]$ by utilizing the information up to time t . The h -step-ahead combined forecast is calculated by the following equation:

$$f_{c,t+h|t} = \sum_{i=1}^n \omega_{it} f_{i,t+h|t}, \quad (3)$$

where $f_{i,t+h|t}$ is the individual forecast over the time window $[t, t+h]$, given the information up to time t , and ω_{it} is the weight on the i th forecast in period t . It is calculated according to the formula

$$\omega_{it} = m_{it}^{-1} / \sum_{j=1}^n m_{jt}^{-1}, \quad \text{where} \\ m_{it} = \sum_{s=T_0}^{t-h} \delta^{t-h-s} E_{it}^2, \quad (4)$$

where δ is the discount factor (when $\delta = 1$, there is no discounting) and E_{it} is the error of the i th forecast at the t th time sample.

Outperformance. Outperformance approach was proposed in Ref. 7. It calculates the forecast combination as $f_c = \sum \omega_i f_i$, where $\omega = [\omega_1, \omega_2, \dots, \omega_N]$ is a simplex of probabilities which can be estimated using the Bayesian approach. In this method, each weight is interpreted as the probability of the corresponding forecast giving the best fit (in a way of the smallest absolute error) on the successive occurrence. Each probability is estimated as the fraction of occurrences, where the corresponding forecasting model has performed the best in the past. Menezes

et al. [10] state that this approach is a robust nonparametric method for achieving differential weights with intuitive meaning, and it performs well when there is relatively little past data, and/or when the decision maker wishes to incorporate expert judgment into the combining weights.

Optimal Method. In the optimal method [2], the calculated linear weights are used to minimize the error variance of the combination. The vector used for combining forecasts is calculated using the following formula:

$$\omega = \frac{S^{-1}e}{e'S^{-1}e}, \quad (5)$$

where e is the $(n \times 1)$ unit vector and S is the $(n \times n)$ covariance matrix of forecast errors. Granger and Ramanathan [11] showed that this method is equivalent to least squares regression in which the constant is suppressed, and the sum of weights has to be equal to one. The shortcoming of this method is that it is necessary to have appropriately estimated S . In practice, it is difficult to evaluate S , because it is often nonstationary. In such a case, it is common to estimate it on the basis of a short history of forecasts, and, as a result, the method becomes an adaptive approach to combining forecasts. In optimal (adaptive) with independence assumption method, the estimate of S in Equation (5) is restricted to be diagonal, comprising only the individual forecast error variance. A case where the optimal formula has the additional restriction that no individual weight can be outside the interval $[0,1]$ is called *optimal* (adaptive) with restricted weights.

Regression. Regression has several variations and extensions; however, overall, it is a simple and flexible method. It is common when combining forecasts to use the constituent forecasts as regressors in the ordinary least squares (OLS) regression with the inclusion of a constant. Granger and Ramanathan [11] stated that it has an advantage over the popular optimal method. The advantage is that an unbiased combined forecast is produced regardless of whether

the constituent forecasts are biased. This can be achieved when one combines the individual forecasts in such a way that their individual errors cancel out. A special case where the least squares regression is done with the inclusion of a constant but the weights are constrained to sum up to one is called *regression with restricted weights*.

Weights are estimated by applying regression on the target variable f_τ on the N -vector of forecast $\hat{f}_{\tau|\tau-1}$ using data over period $\tau = 1, \dots, T$:

$$\hat{\omega}_T = \left(\sum_{\tau=1}^{T-1} \hat{f}_{\tau+1|\tau} \hat{f}_{\tau+1|\tau}' \right)^{-1} \times \sum_{\tau=1}^{T-1} \hat{f}_{\tau+1|\tau} f_{\tau+1}. \quad (6)$$

Many authors have proposed different versions of regression. For example, Granger and Ramanathan [11] consider the following three:

$$\begin{aligned} f_{t+1} &= \omega_t^0 + \omega_t' \hat{f}_{t+1|t} + \varepsilon_{t+1}, \\ f_{t+1} &= \omega_t' \hat{f}_{t+1|t} + \varepsilon_{t+1}, \\ f_{t+1} &= \omega_t' \hat{f}_{t+1|t} + \varepsilon_{t+1}, \text{ s.t. } \omega_t' e = 1. \end{aligned} \quad (7)$$

The first and second of these regressions can be estimated by standard OLS, the only difference being that the second equation omits an intercept term, ω_t^0 . The third equation omits an intercept and it can be estimated through constrained least squares.

The disadvantage of this method is that when applied in unbalanced data sets, the performance is very poor. The estimate of the complete covariance matrix for this type of data is infeasible. The way to deal with such cases is to introduce minimum data requirements and trim the set of forecasts. For instance, it can be done by enforcing the requirements to have forecasts from a certain minimum number of common periods.

In order to partially address this issue, Capistran and Timmermann [12] apply a weighting scheme which, for forecasters with a sufficiently long track record, uses weights that are inversely proportional to their historical MSE-values while using equal weights

for the remaining forecasters (normalized so that the weights add up to one).

Shrinkage. Shrinkage methods have been widely used in forecasting, where the weights are computed as an average of the recursive OLS estimator of the weights [11] and equal-weighting. However, the shrinkage forecasts have the following form:

$$\begin{aligned}\omega_t^i &= \lambda_t \hat{\omega}_t^i + (1 - \lambda_t)(1/N_t), \\ \lambda_t &= \max(0, 1 - \kappa N_t / (T - 1 - N_t - 1)),\end{aligned}\quad (8)$$

where $\hat{\omega}_t^i$ is the least squares estimator of the weight of the i th model in the calculated combined forecast, for example from one of the regression in Equation (7); κ defines the extent of the shrinkage, where the larger values of κ result in a lower λ_t and consequently in a greater degree of shrinkage toward equal weights. When the sample size, T , approaches to the number of forecasts, N , a larger weight is assigned to the least squares estimate. Because this approach is based on the least squares estimator, it faces the same problem as the underlying method. Contrarily, when values of T and N are fixed, greater values of κ coincide with a larger extent of shrinkage leading to equal-weighting (smaller λ_t), and thus this method exhibits some of the problems associated with using equal weights.

Time-Varying Parameter Forecasts. The TVP models usually have a state space form. The state space representation allows unobserved variables to be involved and be evaluated with the observable model. To estimate the time-varying coefficient in forecast regression, the Kalman filter is used.

Stock and Watson [13] modified the approach of combining forecast proposed in Ref. 11, that is, they imposed a zero intercept and extended to have TVPs:

$$f_{s+h}^h = \omega_{1t} \hat{f}_{1,s+h|s}^h + \cdots + \omega_{nt} \hat{f}_{n,s+h|s}^h + \varepsilon_{s+h}^h, \quad (9)$$

where $\omega_{it} = \omega_{it-1} + \eta_{it}$ and η_{it} are serially uncorrelated, uncorrelated with ε_{s+h}^h , and

uncorrelated across i . Essentially, the relative variance $\text{var}(\eta_{it})/\text{var}(\varepsilon_{s+h}^h)$ can be estimated but with many forecasts; its estimation was not reliable enough, so, instead, the authors set the relative variance to $\text{var}(\eta_{it})/\text{var}(\varepsilon_{s+h}^h) = \phi^2/n^2$, where ϕ is a chosen parameter. Larger values of ϕ lead to larger time variation. The initial distribution of ω_{it} settles each weight to $1/n$ with zero variance; taking the limit when $\phi = 0$, the TVP combination forecast reduces to the combined forecast given by simple mean combination.

Nonlinear Methods

The nonlinear combining forecast has been applied widely in recent years [14–16]. In this section, we discuss some of the most prominent methods used for nonlinear combination of forecasts.

Artificial Neural Networks. An artificial neural network (ANN) is a mathematical model inspired by biological neural networks. It is composed of an interconnected group of artificial neurons working together to solve specific problems in fields such as pattern recognition or data classification. In most cases, an ANN is an adaptive system that changes through a learning process.

ANN can be seen as a nonlinear statistical data modeling tool that can be used to model complex nonlinear relationships between a set of individual forecasts and the variable being forecasted. Let $f_{j,t}$ denote the forecast from model j for time t ; $\bar{d}$ and S_d denote the in-sample mean and in-sample standard deviation of the variable being forecasted out-of-sample. In Ref. 17, the following ANN model was applied for forecasts combination:

$$Z_{j,t} = (f_{j,t} - \bar{d})/S_d, j \in \{1, 2\}, \quad (10)$$

$$\begin{aligned}\Psi(z_t, \gamma_i) &= \left(1 + \exp \left[- \left(\gamma_{0,i} + \sum_{j=1}^2 \right) \right. \right. \\ &\quad \left. \left. \times \gamma_{1,i,j} z_{j,t} \right] \right)^{-1},\end{aligned}\quad (11)$$

$$F_t = \beta_0 + \sum_{j=1}^k \beta_j f_{j,t} + \sum_{i=1}^p \delta_i \Psi(z_t, \gamma_i),$$

$$k \in \{0, 2\}, \quad p \in \{0, 1, 2, 3\}. \quad (12)$$

In Equation (10), the individual forecasts are standardized. This procedure and the appropriately selected γ 's undertake that Ψ in Equation (11) usually coincides with the value close to 0.5. The final combined forecast is given in Equation (12). Equation (12) can be easily implemented by neural networks with value of some γ . One way to select γ is to assign a random number with uniform generator from $[-1, 1]$. The parameter δ can be evaluated by applying the least squares technique.

Clustering. Clustering-based forecast methods were applied by some authors [18,19] to sales data analyzed as time series. The common feature of these methods was the usage of past sales data for clustering time series. Kumar [20] proposed the simple clustering method based on the trade-off between decreased variance and increased bias due to combining, where the similarity in the next period forecast and its variance to determine clusters of time series are used. The goal is to minimize the MSE of forecasts. The total MSE for all k clusters is given by

$$\text{MSE}(C_1, \dots, C_k) = \sum_{j=1}^k \sum_{i \in C_j} \left[(\mu_i - \bar{\mu}_{C_j})^2 + \frac{\sigma_i^2}{n_j} \right], \quad (13)$$

where $n_j = |C_j|$ and $\bar{\mu}_{C_j} = \frac{1}{n_j} \sum_{i \in C_j} \mu_i$. Unfortunately, μ_i and σ_i are unknown and they are estimated from data. Replacing μ_i and σ_i in Equation (13) by estimates y_i and s_i^2 , the objective function of clustering is as follows:

$$\min_{C_1, \dots, C_k} = \sum_{j=1}^k \sum_{i \in C_j} \left[(y_i - c_j)^2 + \frac{s_i^2}{n_j} \right], \quad (14)$$

where $c_j = \frac{1}{n_j} \sum_{i \in C_j} y_i$. The first term (i.e., the bias) $\sum_{j=1}^k \sum_{i \in C_j} (y_i - c_j)^2$ decreases with

decreasing number of data points in each cluster, and this leads to a larger number of clusters. The second term (variance) $\sum_{j=1}^k \sum_{i \in C_j} \frac{s_i^2}{n_j}$ decreases with increasing number of data points in each cluster and this leads to a smaller number of clusters. This approach is based on the trade-off between the bias and the variance of combining forecasts from multiple items.

In order to overcome the disadvantages of this simple clustering method, Kumar proposed the weighted average clustering method, where the weight of forecast is given as the inverse of its variance. So the weighted average forecast for items in cluster C_j is calculated as follows:

$$c'_j = \frac{\sum_{i \in C_j} \frac{y_i}{s_i^2}}{\sum_{i \in C_j} \frac{1}{s_i^2}}. \quad (15)$$

In such a case, the new clustering criterion has the following form:

$$\begin{aligned} & \min_{C_1, \dots, C_k} \text{WMSE}(C_1, \dots, C_k) \\ &= \min_{C_1, \dots, C_k} \sum_{j=1}^k \sum_{i \in C_j} \frac{1}{s_i^2} \\ & \quad \times \left[(y_i - c'_j)^2 + \frac{1}{\sum_{i \in C_j} \frac{1}{s_i^2}} \right] \end{aligned} \quad (16)$$

The author showed that simple clustering reduced the overall MSE of forecast by 7.6%, from 26.1% to 18.5%, and weighted clustering reduced it further by 3.7%, from 10.5% to 6.8%.

Fuzzy Systems. Fuzzy control systems are systems based on fuzzy logic, a language that allows incorporation of qualitative knowledge into solving some specific problem. Fuzzy logic-based control systems offer a general framework for implementation of linguistic IF-THEN rules.

In order to combine forecasts, Fiordaliso [21] used the Takagi–Sugeno fuzzy system, a special class of fuzzy systems whose output of each rule is a scalar. A typical single fuzzy rule in first order has the form

$$\text{IF } X \text{ is } A \text{ THEN } Z = h(X), \quad (17)$$

where A is a fuzzy set with membership function m_A and $h(X)$ is a polynomial of order one in the components X_i of the input variable X . The output f_c of such system with r rules [IF X is A_k THEN $Z = B_k(X)$] can be written as follows:

$$f_c = \frac{\sum_{k=1}^r m_{A_k}(X) B_k(X)}{\sum_{k=1}^r m_{A_k}(X)}, \quad (18)$$

where

$$B_k(X) = b_k(0) + b_k(1)X_1 + \dots + b_k(p)X_p. \quad (19)$$

Letting X_j denote the forecasted value $f_j(t)$ and using Equation (19), the combined forecast can be expressed as $f_c = \omega_0(t) + \omega_1(t)f_1(t) + \dots + \omega_p(t)f_p(t)$, where

$$\omega_j(t) = \frac{\sum_{k=1}^r m_{A_k}(f(t)) b_k(j)}{\sum_{k=1}^r m_{A_k}(f(t))}. \quad (20)$$

This property can be achieved only with the special structure of Takagi–Sugeno first order system because of its linear local model.

Every rule in the given system implements a particular combined forecast according to Equation (18). The input of each rule to combining forecasts is determined by the membership function. Fiordaliso [21] used the p -dimensional generalized Gaussian-type membership functions for the coding of the linguistic terms:

$$m_{A_k}(X) = G\left(\|X - \mu_k\|_{S_k}^2\right), \quad (21)$$

where μ_k is the center of the Gaussian, G is defined by $G(x) = \exp(-x)$ and $\|X\|_{S_k}$ is

the weighted norm of X defined by $\|X\|_{S_k}^2 = X^T S_k^T X$, where S_k is a square matrix corresponding to a specific metric in the multidimensional input space, which is responsible for the linear transformation of individual forecasts. In such a case, the system can be considered as a smooth switching regression model, where two regimes can be active at the same time [21]. In order to allow monitoring, the importance of each rule k in the inference process, a nondecreasing function $g(\rho_k)$ with its values in the $[0, 1]$ can be introduced in the final output f_c :

$$f_c = \frac{\sum_{k=1}^r g(\rho_k) m_{A_k}(X) B_k(X)}{\sum_{k=1}^r g(\rho_k) m_{A_k}(X)}. \quad (22)$$

A small $g(\rho_k)$ value can be used to remove a particular rule from a system; that is, this rule will make a very small contribution to the combined forecast.

Palit and Popovic [22] proposed performing a nonlinear forecast combination based not only on fuzzy logic approach but also on neuro-fuzzy approach. In the neuro-fuzzy approach, they used the fuzzy logic system:

$$f(x) = \frac{\sum_{l=1}^M [y^l z^l]}{\sum_{l=1}^M [z^l]}, \quad (23)$$

$$z^l = \prod_{i=1}^n \exp\{-(x_i - c_i^l)^2 / \sigma_i^l\},$$

which is based on the Gaussian membership function, singleton fuzzifier, product inference rule, and center of area defuzzifier. It is equivalent to the multilayer feedforward network, described in Ref. 23 as neuro-fuzzy network, with the means c_i^l , the variances σ_i^l , and the fuzzy region centers y^l as the adjustable parameters of the network.

The superiority of combining forecasts based on neuro-fuzzy approach to any individual forecast involved in the combination was demonstrated by calculating performance indices.

Rule-Based Approach. Some experts [Makridakis and Hibon [24], Bunn and Wright [25]] advise to combine the judgment and quantitative or statistical methods to get better forecast accuracy. Collopy and Armstrong [26] proposed the rule-based forecasting, that is, the procedure that applies forecasting competence and knowledge to make forecasts according to the features of the data. Their proposed rule is based on integrated strategies such as

- using features of the series to establish weights for combining forecasts;
- using heuristics to establish parameters for an exponential smoothing model;
- using separate models for long-range and short-range forecasts;
- damping the trend under certain conditions;
- incorporating domain knowledge in extrapolation.

They created a rule base of 99 rules with reference to report analysis of five experts on forecasting methods. Four extrapolation methods are used to produce combinations of forecasts.

The authors report 42% less errors for rule-based forecasting than those from equal weights combining and this improvement is statistically significant. It should be noted that improvement depends on the condition of the data.

CONCLUSIONS

A very important question is whether combining forecasts is really worth the effort. In other words, one would like to know if the intuitive statement “many predictors are better than one” is always confirmed in practice. Some researchers prefer combining different data sets versus combining different forecasts. In any case, one should be aware that the comparison between combining data sets and combining forecasts might not always be fair, since different sources of data sets might be expensive to obtain or even infeasible.

In all respects, one should be always extremely cautious when combining forecasts. In Ref. 27, Armstrong suggests some practical rules for aggregating forecasting methods: combining at least five methods, using some formal procedure for combining forecasts, using trimmed means, utilizing prior experience to adjust weights when taking means, and using manually adjusted weighted means when there is some strong evidence from the application.

Also, on a total of 30 studies from 1950 to 2000, he reports that there was on average 12.5% error reduction (ranging from 3.4–24.2%) when combining forecasts was employed.

However, there have been some researchers who have reported negative results (meaning that individual forecasts outperformed the combined). Although there is no mathematical proof for the one or the other side, Granger, who was the one who first formally introduced the concept in his review paper [8], says “if that is true (individual forecasts are better than combined), this would be very disturbing for forecasters as it would mean that very simple methods of forecasting are difficult to improve upon.”

COMBINING SCENARIO PLANNING WITH MULTIATTRIBUTE DECISION MAKING

PAUL GOODWIN
School of Management,
University of Bath, Bath,
Somerset, United Kingdom

Companies and other organizations have to make long-term strategic decisions in a highly uncertain environment. Economic booms and slumps, unforeseen technological developments, changes in government policies, the actions of competitors, and many other factors that are beyond the control of the decision maker can all lead to outcomes that were totally unexpected when the original plans were laid. Businesses that have been highly successful for decades can suddenly find themselves in difficulties, while new companies, which are able to exploit changes in the environment, come to dominate their markets.

However, uncertainty is not the only factor that challenges strategic decision makers. Many decisions will be made with the intention of achieving several objectives. Sometimes these objectives will reflect the different perspectives of the various stakeholders in the organization, such as the shareholders, the senior managers, the non-managerial employees, and the customers. Typical objectives may include maximizing profits, maximizing market share, minimizing pollution, maximizing employee welfare, minimizing risk, and maximizing customer satisfaction. Many of these objectives are likely to conflict. For example, minimizing pollution may come at the expense of reduced profits. This means that decision makers will need to make trade-offs.

Research by psychologists suggests that unaided decision makers often have difficulties in handling the complexity presented by both uncertainty and multiple objectives [1, 2]. When confronted with this complexity, they resort to the use of simplifying

mental strategies, or heuristics. While these heuristics allow decisions to be made quickly and with relatively little cognitive effort, they are prone to biases. As a result, probabilities are misjudged and some objectives may receive insufficient attention, while others are overweighted. In addition, decision makers may also be subject to strategic (or cognitive) inertia, which is reflected in a tendency to continue with existing strategies even when changes in the organization's environment mean that these strategies are no longer appropriate [3].

All of this suggests that managers planning their future strategies can benefit from some form of decision support. Multiattribute decision analysis provides this support by breaking complex decisions down into smaller and, hopefully, easier problems, thereby helping managers to address the trade-offs they need to make between their objectives. Scenario planning also provides a structure to help managers to explore the uncertainties that they face, without relying on probability estimation. In the following sections, we consider how the benefits of the two approaches can be combined to allow managers to plan and adapt their strategies with enhanced insight and with a greater awareness of the challenges posed by an ever-changing environment.

SCENARIO PLANNING

Scenario planning avoids the problems that decision makers have in estimating probabilities for future events. Instead, a series of stories are constructed, usually in structured sessions involving groups of managers with a facilitator. Independent-minded experts (referred to as "remarkable people") who might challenge an organization's current thinking may also be involved in the process [4]. Each story describes how the future might unfold between the date when the strategic decision is made and the planning horizon. While the particular combination

of events described by each scenario is extremely unlikely to occur, it is hoped that, collectively, these stories will encompass the range of possible futures.

There are several approaches to the writing of scenarios but all involve a formal structured procedure [5]. The “intuitive logics” method is one approach that is widely used. Wright and Cairns [4] give a detailed and comprehensive explanation of how to apply this method, but the key steps are demonstrated below using an example relating to a manufacturer of electric cars.

1. *Identify the focal issue and time frame which the scenarios are intended to cover.*

The focal issue in this case is: “the viability of the business for the next ten years.”

2. *Identify the driving forces that will impact on the focal issue.*

Driving forces that are relevant here include:

- a. The extent to which there are improvements in battery technology.
- b. Future movements in oil prices.

- c. The extent to which governments provide tax incentives for purchasers of electric cars.

- d. The extent to which battery-recharging points become widely available in public places.

- e. The extent to which there are stricter international targets on greenhouse gas emissions.

3. *Cluster these driving forces into factors by exploring how they interrelate. Give each factor a name.*

This step is intended to consider how the driving forces interact. In some cases, the outcome of one driving force will have an effect on the outcome of another.

Figure 1 shows how driving forces can be arranged into a factor called “level of market penetration of electric cars.” For example, the extent to which there are stricter international targets on emissions will affect the extent to which governments encourage the development of an infrastructure of charging points in public places for electric vehicles. This, in turn, will affect consumers’ relative preference for electric cars over other types of vehicle.

Figure 1. A factor displaying a typical cluster of driving forces.

Usually, several factors will be identified. For example, in this case, we may have other clusters relating to the cost of manufacture, the level of entry into the industry by competing manufacturers, world economic recession or growth, and so on.

4. *Identify extreme outcomes for each factor.*

Examples of extreme outcomes are as follows.

Outcomes leading to high profitability for the manufacturer

Very high market penetration for electric cars.

Unit manufacturing costs fall.

Few manufacturers enter market.

World economic growth.

Outcomes leading to poor profits for the manufacturer

Little or no market penetration for electric cars.

Unit manufacturing costs rise as a result of increased commodity prices.

High levels of international competition with other manufacturers.

World economic recession.

5. *Plot the factors on a graph to identify those that have the maximum potential impact on the focal issue and the greatest uncertainty about this impact.*

Figure 2 shows a typical graph that assumes that we have identified eight factors, including the level of market penetration that we identified earlier.

It can be seen that the two factors, “market penetration” and “world economic recession or growth,” are judged to have both the highest impact and the greatest level of uncertainty. We now list the extreme outcomes associated with these factors and give them a label.

Market penetration: A1: High penetration

A2: Very low penetration

World economy B1: Growth

B2: Recession

We then check that the four combinations of outcomes: A1 & B1, A1 & B2, A2 & B1, and A2 & B2 are plausible, in that they could coexist in the future. If they could not, then we need to review the earlier steps.

6. *Write a scenario based on each of the four combinations and give each scenario a name.*

Each scenario should also include other high impact factors that are regarded as relatively certain. For example, the effect of manufacturing costs should be included in all scenarios, given its importance. The scenario for A1 & B1, which has been named “Green Boom,” is as follows.

“Greater world demand for oil leads to significantly higher prices. In many countries, electric cars also carry low rates of taxation when purchased and licensed. Developments in battery technology lead to longer intervals between charging and higher sales lead to significant falls in the manufacturing costs of vehicles. Environmental concerns over pollution also lead to increased taxes on oil-based fuels in many countries. In addition, governments subsidise the development of infrastructures to support the recharging of electric cars, including the widespread availability of power points in car parks and at supermarkets. World economic growth stimulates international demand, but competing manufacturers are slow to catch up with the technologies needed to develop mass production of electric vehicles.”

Three other scenarios would be developed around the other combinations of extreme outcomes. We will refer to the scenario based on outcomes A1 & B2 as “Electrics dominate in tough times” and those based on A2 & B1 and A2 & B2 as “Boom bypasses electrics” and “Rocky road ahead.” Collectively, these scenarios would attempt to bound the range of possibilities of what might be expected to happen in the specified time frame. They can then be used to inform strategic planning.

Proponents of scenario planning argue that it brings a number of important benefits to strategic decision making. Stories may be a natural way for humans to make sense of

Figure 2. Impact-uncertainty plot.

the world and they provide an explanation of why particular futures might unfold. Once a scenario has been read, it may alert managers that events are moving in a particular direction allowing early contingency plans to be laid to deal with potential problems or new business opportunities to be embraced. In addition, the process of scenario development allows a diversity of views about the future to be reflected so that minority opinions are considered, while the presence of remarkable people may counter strategic inertia.

However, scenario planning lacks a theoretical underpinning and different practitioners tend to construct scenarios in different ways. There is also the danger that, as more detail is added to scenarios, they appear to become more plausible and hence more probable when, in fact, the opposite is the case [1]. Most importantly, the basic scenario planning process does not provide guidance as to how alternative strategies should be evaluated. Usually, the evaluation is informal. The range of scenarios are regarded as being analogous to a wind tunnel within which alternative strategies can be assessed for their robustness and success under the various conditions that might prevail in the future. But where the strategic decision depends on a plurality of objectives, it is difficult for unaided decision makers to carry out such an assessment, given the multiplicity of scenarios and objectives that have to be considered.

COMBINING SCENARIO PLANNING WITH THE SIMPLE MULTIATTRIBUTE RATING METHOD

In order to provide support for decision makers faced with the need to evaluate strategies over multiple objectives and scenarios, Goodwin and Wright [6] suggested an approach that is intended to be simple and transparent. This combines the simple multiattribute rating technique (SMART) method [3, 7] with scenario planning. We illustrate the main stages of the process for the electric car manufacturer.

Stage 1: Identify objectives.

The electric car manufacturer identifies the following three objectives.

- a. Maximize the sustainability of profits in the long term.
- b. Minimize the impact of its operations on the environment.
- c. Maximize its share of the car market.

Stage 2: Design alternative strategies.

The manufacturer is considering one of the following three strategies to pursue.

- a. Produce a limited range of small family electric cars for the domestic market (LIMITED).
- b. Produce a wider range of cars and aim for international sales (WIDE RANGE).
- c. Diversify into hybrid and petrol vehicle production for the international market (DIVERSIFY).

Stage 3: For each objective:

- a. Rank all the strategy/scenario combinations from best to worst.
Table 1 shows these ranks for each objective.
- b. Allocate a score of 100 to the best strategy/scenario combination and 0 to the worst.
- c. Allocate scores between 0 and 100 to measure the performance of intermediate strategy scenario combinations.

These scores are shown in Table 2

Stage 4:

- a. List the objectives and for each one consider the improvement between the worst-performing strategy (scoring 0) and the best (scoring 100). Rank these improvements in order of importance or desirability.

Table 3 shows these ranks.

- b. Attach a weight of 100 to the objective that offers the most important or desirable improvement and obtain weights for the other objectives by comparing the importance of the improvements they offer against the maximum weight of 100. Normalize the weights so that they sum to one by dividing each weight by the sum of the weights.

Table 4 shows the weights obtained for the electric car manufacturer.

Table 1. Ranking the Performance of Strategies for each Objective and Scenario

Strategy	Green Boom	Electrics Dominate in Tough Times	Boom Bypasses Electrics	Rocky Road Ahead
Objective: maximize sustainability of profits in long-term scenarios				
LIMITED	2	5	8	11
WIDE RANGE	1	4	9	12
DIVERSIFY	3	6	7	10
Objective: minimize environmental impact scenarios				
LIMITED	6	5	1 =	1 =
WIDE RANGE	8	7	3 =	3 =
DIVERSIFY	12	11	9 =	9 =
Objective: maximize share of car market scenarios				
LIMITED	5 =	5 =	11 =	11 =
WIDE RANGE	3 =	3 =	9 =	9 =
DIVERSIFY	1 =	1 =	7 =	7 =

1 represents best performance. Equals signs indicate where the ranks are tied.

Table 2. Scoring the Performance of the Strategies on each Objective

Strategy	Green Boom	Electrics Dominate in Tough Times	Boom Bypasses Electrics	Rocky Road Ahead
Objective: maximize sustainability of profits in long-term scenarios				
LIMITED	85	50	25	10
WIDE RANGE	100	60	20	0
DIVERSIFY	70	40	30	15
Objective: minimize environmental impact scenarios				
LIMITED	65	70	100	100
WIDE RANGE	55	60	80	80
DIVERSIFY	0	20	30	30
Objective: maximize share of car market scenarios				
LIMITED	50	50	0	0
WIDE RANGE	60	60	5	5
DIVERSIFY	100	100	20	20

Table 3. Ranking the Importance of the Improvements

Improvement	Rank of Improvement
Worst profit sustainability to best	1
Minimize environmental impact	2
Worst share of electric market to best	3

Table 4. Assigning Weights to the Objectives

Improvement	Rank of Improvement	Weight	Normalized Weight
Worst profit sustainability to best	1	100	0.59
Minimize environmental impact	2	60	0.35
Worst share of electric market to best	3	10	0.06
	Total	170	1

Stage 5: For each strategy / scenario combination, use the performance scores and weights to determine a weighted aggregate score.

For example, Table 5 shows how the score has been obtained for the LIMITED strategy under the Green Boom scenario.

Stage 6: Produce a table of strategy / scenario aggregate scores and use this to assess and compare the strategies' performances, paying particular attention to the robustness of performance over the range of scenarios.

Table 6 shows the resulting scores (which have been rounded to whole numbers).

It can be seen that the DIVERSIFY strategy is dominated by the others. Whichever scenario prevails, its performance is worse than the other two. The LIMITED strategy is likely to be more appealing to a risk averse decision maker. Although it does not perform quite as well as WIDE RANGE in the first two scenarios, it performs much better in the others so it appears to carry less risk.

Stage 7: Perform sensitivity analysis. This is because the scores and weights are likely to be based on rough estimates, or there may be disagreements within

the decision-making team, so it is important to determine the effect of variations in these estimated values.

For brevity, this will not be demonstrated here.

Goodwin and Wright [3], who first proposed the method, suggest that in practice it is likely that the process will need to switch backward and forward between the stages as decision makers develop an increased understanding of the problem and wish to revise their earlier judgments.

EXTENSIONS OF THE METHOD AND ALTERNATIVES

The above-outlined basic method has a number of limitations. In some circumstances, it can require a large number of judgments to be elicited from decision makers. Wright and Cairns [4] have suggested a simpler form that only involves the assessment of ranks for the performances and objectives (this avoids stages 3b, 3c, and 4b). This method is likely to be most appropriate where the gaps between the performances of the strategies in the different scenarios are fairly even and the same applies to the gaps between the weights assigned to the objectives. It will be less appropriate where, for example, strategy A would have been allocated a

Table 5. Calculating a Weighted Aggregate Score for a Strategy

Objective	Score	Weight	Score × Weight
Profit sustainability	85	0.59	50
Environmental impact	65	0.35	23
Market share	50	0.06	3
—	—	—	Weighted aggregate score = 76

Table 6. Weighted Aggregate Scores for each Strategy under each Scenario

Strategy	Scenarios			
	Green Boom	Electricity Dominate in Tough Times	Boom Bypasses Electricity	Rocky Road Ahead
LIMITED	76	57	50	41
WIDE RANGE	82	60	40	28
DIVERSIFY	47	37	29	21

weight of 100, with strategy B coming a close second with a weight of 90, while strategy C would have lagged far behind with a weight of only 20. Karvetski *et al.* [8] also demonstrated a method designed to reduce the number of judgments that needed to be elicited from decision makers. This was also based on ranks, though the way that decision makers' preferences were inferred from these ranks differed from the Wright and Cairns approach.

Goodwin and Wright's method makes the strong assumption that the relative importance of the objectives will be the same under different scenarios. In some situations, this may not be the case. For example, the objective of minimizing dependency on oil may be seen to be relatively less important in a scenario of increased availability of oil, resulting from the discovery of extensive new oil fields, than in a scenario of declining world oil resources. Where this is the case, Montibeller *et al.* [9] suggest extending the approach by developing separate multiattribute models for each scenario. They applied their extended methods to two Italian companies. The application by Karvetski *et al.* [8] was also able to consider changes in preferences across scenarios, while still minimizing the number of judgments required from decision makers.

Some authors recommend that decision makers should select strategies on the basis of how robust they are across the range of scenarios. A strategy that performs *reasonably* well, whatever happens in the future, is deemed to be superior to the one that performs superbly in some scenarios, but disastrously in others. However, researchers have yet to resolve how robustness should be measured and the extent to which it is desirable.

Scenario analysis and multiattribute decision analysis have been combined in several other ways. For example, Durbach and Stewart [10] proposed an alternative approach that involved the integration of goal programming, rather than SMART, with scenarios. Other researchers have combined the two approaches in order to appraise the relative desirability of alternative scenarios (e.g., [11]). In their analysis, it is assumed that the

decision maker has a choice between scenarios, rather than regarding them as outcomes that are largely or wholly beyond the decision maker's control.

CONCLUSIONS

In a volatile and uncertain world, scenario planning can be an attractive tool enabling managers to explore the range of plausible futures that may impact on their organization and sensitizing them to potential opportunities or threats. Alternative strategies can be evaluated under different conditions that may apply in the future, but where there are multiple objectives, this evaluation may be cognitively demanding and lead to biases in the decision-making process. Combining multiattribute value analysis with scenario planning can help to overcome these biases, allowing managers to address the full range of issues that may be relevant to their planning and providing a documented rationale for any decisions that they make.

COMMON FAILURE DISTRIBUTIONS

SATYANSHU KUMAR UPADHYAY
Department of Statistics, DST Centre
for Interdisciplinary Mathematical
Sciences, Banaras Hindu
University, Varanasi, India

INTRODUCTION

A failure (or life) time distribution is an attempt to describe mathematically the length of life of an item or an organism under study. That is, a probability distribution of a certain form is usually assumed to provide among many other characteristics the reliability or survival probability of the item under consideration at each time t . However, since there are many physical or biological causes that individually or collectively may be responsible for the failure of an item or an organism at any given instant, and since it is not generally possible to isolate these causes, the choice of a failure distribution is definitely an art. The selection of failure distribution in a particular situation is thus subject to uncertainty and is often decided based on empirical considerations, although it does not necessarily imply the absolute correctness of the assumed model. Sometimes, we may have information about the ageing or failure processes in the population that may ultimately suggest several forms of failure distributions but often not able to narrow our consideration to specific family of models [1].

To fix the idea, let T be a nonnegative random variable representing the failure time of an item or an organism. Five different functional forms may normally be used for representing the failure distribution of T . These may be listed as the survival function, the probability density function, the hazard function, the cumulative hazard function, and the mean residual life function, the last one representing the remaining life given survival until time t . If $f(t)$ denotes the probability density function of the random variable T , the explicit expressions for the

survival function, the hazard function, the cumulative hazard function, and the mean residual life function can be given as

$$S(t) = P(T \geq t), \quad (1)$$

$$h(t) = \frac{f(t)}{S(t)}, \quad (2)$$

$$H(t) = \int_0^t h(u) du, \quad (3)$$

$$r(t) = E(T - t | T \geq t), \quad (4)$$

respectively, where the random variable T is assumed to be continuous. It is to be noted that these are not the only representations, the other representations, although not often in practice, may include the moment generating function, the characteristic function, and the Mellin transform. A detailed discussion of these various concepts can be found in Ref. 2.

It is not always clear whether a continuous or a discrete failure model should be used for the random variable T under consideration though the discrete models are advocated only in very few situations. An example can be the assessment of software reliability where the time can be modeled discretely. The five distributional representation concepts mentioned in the preceding lines apply to discrete distributions as well. Except for the probability density function which is now replaced by the probability mass function, the names for the other four representations remain the same.

There are numerous parametric models used in the analysis of failure time data and in the problems related to the modeling of ageing or failure processes. Among univariate class of models, a few particular distributions play a central role because of their demonstrated usefulness in a wide variety of situations. Exponential, Weibull, gamma, lognormal, generalized gamma, and so on, are some commonly available continuous distributions. The important discrete distributions may include geometric, binomial, Poisson, negative binomial, hypergeometric, multinomial, and so on,

among others. Besides, there are several other models that have been used successfully in lifetime contexts based on specific applications or specific hazard rate shapes. Multivariate distributions are also often used especially in situations where two or more related failure time variables are of interest simultaneously. Situations may also arise where the failure times are related to or affected by several concomitant or regressor variables and the experimenter seeks for an appropriate regression model for best representing the data. Such situations arise, for example, in accelerated testing or medical data analyses where the covariates such as age, sex, physical conditions, and reports of pathological or other examinations are expected to affect the patients' conditions. Owing to space restriction, we shall be discussing a very few models named above though the interested readers may refer to Refs 2–5 for other related details.

As mentioned, hazard rate, which represents the instantaneous probability of failure, is an important characteristic to specify a failure model. Models with increasing hazard rate are used the most. One reason for this may be attributed to the fact that the interest often centers on a period in the life of an item or an individual over which some kind of gradual increase in the age takes place, yielding an increasing failure rate. In addition, populations that reflect a bathtub shape failure rate are sometimes purged of weak individuals, leaving a reduced population with an increasing failure rate. For example, manufacturers often use a “burn-in” process in which items are subjected to a brief period of operation before being sent to customers. In this way, flawed items that would fail very early are removed from the population, this frequently leaves a residual population in which individuals, or items or devices exhibit gradual ageing, with an increasing failure rate.

Models with constant failure rate are important and have a particularly simple structure. Models with decreasing failure rate are less common, but are sometimes used especially in situations where early failures dominate the processes. If items (or individuals) are kept over some fairly

long initial period of use, these result in the decreasing failure rate. One can also have situations where the process requires all the three shapes simultaneously giving rise to bathtub-shaped hazard rates. Models having capability of representing all three shapes simultaneously are important but usually difficult in many ways. Nonmonotone failure rate other than bathtub-shaped curves are less common but advocated sometimes in the literature [1,6].

A FEW COMMON CONTINUOUS FAILURE DISTRIBUTIONS

The Exponential Distribution

The exponential distribution has been widely used in the areas ranging from studies on the lifetimes of manufactured items [7] to research involving survival or remission times in some diseases and perhaps it has been the most widely used model in reliability studies and survival analysis in general [1,4]. The desirability of the exponential distribution is due to its simplicity and its inherent association with the theory of Poisson process [4]. The applicability of the distribution is, however, limited to some extent due to its lack of memory property which requires that previous use of an item or an organism does not affect its future use [8]. That is, if a device is functioning at time t , it is as good as a new one and the remaining life has the same exponential distribution.

The exponential distribution characterized by a constant hazard rate λ (> 0) has the probability density function given by

$$f(t) = \lambda \exp(-\lambda t), \quad t > 0. \quad (5)$$

The distribution has mean λ^{-1} and variance λ^{-2} and its survival function is available in closed form, that is, $S(t) = \exp(-\lambda t)$. An alternative formulation of the model is also sometimes used with scale parameter θ replacing the parameter λ^{-1} . The distribution when θ equals unity is called the *unit exponential distribution* that has been shown in Fig. 1. Clearly, if T has the density (Eq. 5), λT has a unit exponential distribution.

Figure 1. Probability density function of the unit exponential distribution.

Historically, the exponential distribution can be considered as the first widely used model especially in the context of failure time data analyses exactly as normal distribution does in other areas. This was partly because of the availability of simple statistical methods for it [9] and partly because the distribution appeared to provide suitable representation for the lifetimes of many things, such as various types of manufactured items [1]. The assumption of constant hazard rate is, however, a restrictive criterion and it was lately realized that many inferences are sensitive to departures from the exponentiality. This has led to greater caution in the use of the distribution.

Inferences for the exponential distribution are available in bulk both in the context of classical [1,4] and the Bayesian paradigm [10]. The obvious reason in case of former is the availability of closed form expression for the sufficient statistic of the parameter θ . The inferences for the latter paradigm are also often available in closed form or at most it may involve a single dimensional integral for some typical selection of the prior distribution for the parameter θ [10].

The Weibull Distribution

The applicability of the exponential distribution is limited because of the assumption of

a constant hazard rate, whereas the Weibull family can include increasing and decreasing hazard rates as well. The distribution is perhaps the most widely used model for lifetime data analyses. Its suitability in connection with the lifetimes of a wide variety of manufactured items, including vacuum tubes, ball bearings, and electrical insulating materials has been discussed by several authors [1,4]. The distribution has wide applicability in several biomedical studies as well. A few such situations include the time to the occurrence of tumors in human population, survival times of patients suffering from carcinoma after receiving a treatment, say chemotherapy, and so on [1,11]. The probability density function of the Weibull distribution has the form

$$f(t | \alpha, \beta) = \frac{\beta}{\alpha} \left(\frac{t}{\alpha} \right)^{\beta-1} \times \exp \left[- \left(\frac{t}{\alpha} \right)^{\beta} \right], \quad \alpha, \beta > 0, t > 0, \quad (6)$$

where α is the scale parameter and β determines the shape of the distribution. If $\beta = 1$, the distribution reduces to the one-parameter exponential distribution and, therefore, it results in constant hazard rate. It can be easily observed that the hazard

rate of the model is decreasing (increasing) in t if $\beta < 1$ ($\beta > 1$). When $\beta = 2$, the hazard rate is a linearly increasing function of t , and the resulting distribution is known as the *Rayleigh distribution*. The survival and the hazard function of the model can be written as

$$S(t | \alpha, \beta) = \exp \left[- \left(\frac{t}{\alpha} \right)^\beta \right], \quad (7)$$

$$h(t | \alpha, \beta) = \frac{\beta}{\alpha} \left(\frac{t}{\alpha} \right)^{\beta-1}, \quad (8)$$

respectively. The mean and variance of the distribution are

$$E(T) = \alpha \Gamma \left(\frac{\beta + 1}{\beta} \right),$$

$$V(T) = \alpha^2 \left[\Gamma \left(\frac{\beta + 2}{\beta} \right) - \Gamma^2 \left(\frac{\beta + 1}{\beta} \right) \right].$$

The shape of the density and hazard rate depends on the model parameters. The Weibull model exhibits a wide variety of shapes for the density, survival function, and the hazard function. Figure 2 shows a typical Weibull density for the case where $\alpha = 1$. The corresponding hazard function is shown in Fig. 3.

Weibull distribution is an extensively rich family in the sense that a large body of literature on both classical and Bayesian methods has successfully evolved out of it. An important reason for this being the nonexistence of any two-dimensional sufficient statistics, in general, for both α and β and, therefore, an enormous possibility exists for producing inferential procedures for the distribution. Although mathematical tractability is often a serious problem involved with the analysis of the model, it appears that the statistical procedures that are relatively easy to use are now available [1,4,12,13]—thanks to the modern computing tools that enabled the routine development of these procedures.

The Gamma Distribution

The gamma distribution is a natural extension of the exponential distribution which is often used in engineering, science, and business applications to model continuous variables that are always positive and skewed. The distribution can be derived by considering the time to occurrence of n th event in a Poisson process or, equivalently, by considering the n -fold convolution of an exponential distribution [4,14]. Actually the distribution is a continuous analog of negative binomial distribution that can be

Figure 2. Probability density function of the Weibull distribution when $\alpha = 1$.

Figure 3. Hazard function for the Weibull distribution when $\alpha = 1$.

obtained by considering the sum of n variables with common geometric distribution. The probability density function of a gamma distribution with parameters α and β is given by

$$f(t | \alpha, \beta) = \frac{1}{\alpha^\kappa \Gamma(\kappa)} t^{\kappa-1} \exp\left(-\frac{t}{\alpha}\right), \quad \alpha, \kappa, t > 0, \quad (9)$$

where $\Gamma(\kappa)$ denotes the complete gamma function. The parameters α and κ are referred to as the *scale* and *shape parameters* of the gamma distribution, respectively.

The survival and the hazard functions of the gamma model are not available in closed forms unless α happens to be integer; however, they may be expressed in terms of a standard incomplete gamma function for which computer subroutines are widely available. The family includes increasing, decreasing, or constant hazard rates depending upon the values of κ . It can be seen that the hazard rate is monotone increasing for $\kappa > 1$, decreasing for $\kappa < 1$, and constant for $\kappa = 1$ and, therefore, the distribution reduces to the one-parameter exponential distribution for the last case. The expressions for the survival and the hazard functions for the

gamma distribution can be written as

$$S(t | \alpha, \kappa) = \frac{\Gamma(\kappa) - \Gamma(\kappa, t/\alpha)}{\Gamma(\kappa)}, \quad (10)$$

$$h(t | \alpha, \beta) = \frac{t^{\kappa-1} \exp(-t/\alpha)}{\alpha^\kappa [\Gamma(\kappa) - \Gamma(\kappa, t/\alpha)]}, \quad (11)$$

where $\Gamma(a, z)$ is the incomplete gamma function given by

$$\Gamma(a, z) = \int_0^z y^{a-1} \exp(-y) dy, \quad a > 0.$$

The probability density function in Equation (9) is bell shaped for $\kappa > 1$, and reverse J shaped for $\kappa \leq 1$. The mean of the distribution is $\kappa\alpha$ and its variance is $\kappa\alpha^2$ and, therefore, the parameter κ may also be interpreted as a square of the reciprocal of the distribution coefficient of variation. The probability density function of the gamma distribution is shown in Fig. 4 for various values of shape parameters, whereas the corresponding hazard rate curves are shown in Fig. 5. These curves are drawn by taking scale parameter α as unity.

Gamma distribution is closely related to chi-square distribution. We can easily see from Equation (9) that if T is distributed according to gamma distribution with shape parameter α and scale parameter unity, $2T$ has chi-square distribution with

Figure 4. Probability density function of the gamma distribution when $\alpha = 1$.

Figure 5. Hazard function for the gamma distribution when $\alpha = 1$.

2α degrees of freedom. For integer values of α , the gamma distribution is also known as *Erlang distribution*. The moments and other properties of gamma distribution can be had from Ref. 15, and the reference also provides the relationship of gamma distribution with several other important distributions.

The use of gamma distribution as a lifetime model is not as common as the corresponding Weibull model. The obvious

reason being the nonavailability of closed form expressions for the survival and the hazard functions. This, in fact, has resulted in more complicated inferential procedures as compared to the same for Weibull distribution. Undoubtedly, the credit goes to the sophisticated computational techniques, most of which were developed in the previous decades especially after the advent of modern computing devices. The classical developments related to the model can

be found in Refs 1 and 4, whereas the corresponding Bayesian results can be seen in Refs 10 and 13 among others.

The Lognormal Distribution

The lognormal distribution initially received little attention in the statistical literature due to its limited applications in some rare situations. However, its importance was lately realized and it became an important model particularly in the area of life testing and survival analysis in spite of its one unattractive feature concerning the hazard rate. References 1, 4, and 12 are worth mentioning texts that detail a systematic accountability of various developments and provide some good references related to the model.

The logarithmic normal distribution implies that the logarithms of the lifetimes are normally distributed. That is, when the random variable T follows two-parameter lognormal distribution with parameters μ , and σ , $\ln(T)$ follows normal distribution with mean μ and variance σ^2 . Thus, the probability density function of T can be written as

$$f(t | \mu, \sigma) = \frac{1}{\sqrt{2\pi}\sigma t} \exp \left[-\frac{1}{2\sigma^2} (\ln t - \mu)^2 \right];$$

$$0 < t < \infty, -\infty < \mu < \infty, \sigma > 0, \quad (12)$$

where $\exp(\mu)$ and σ are the scale and shape parameters, respectively [1].

The hazard rate of the lognormal distribution, as a function of time, is an increasing function followed by a decreasing function, and can be shown to approach to zero for large lifetimes and also at the initial time [4]. Although this feature appears unattractive, the model is found suitable especially when large values of lifetimes are not of interest and the early failures or occurrences dominate. Some of the general properties of this distribution can also be found in Refs 15–17. The expressions for the survival and the hazard functions of the model are not available in closed forms and involve the standard normal distribution function. These expressions can be written as [10]

$$S(t | \mu, \sigma^2) = 1 - \Phi \left(\frac{\log t - \mu}{\sigma} \right), \quad (13)$$

$$h(t | \mu, \sigma^2) = \frac{\phi \left(\frac{\log t - \mu}{\sigma} \right)}{\sigma t - \Phi \left(\frac{\log t - \mu}{\sigma} \right)}, \quad (14)$$

where $\phi(\cdot)$ denotes the standard normal probability density function and $\Phi(z)$ denotes the cumulative distribution function given by

$$\Phi(z) = \int_{-\infty}^z \frac{1}{\sqrt{2\pi}} \exp \left(-\frac{x^2}{2} \right) dx.$$

The mean and variance of the distribution are

$$E(T; \mu, \sigma^2) = \exp \left(\mu + \frac{\sigma^2}{2} \right),$$

$$V(T; \mu, \sigma^2) = (\exp(2\mu + \sigma^2))(\exp(\sigma^2) - 1),$$

respectively. Figure 6 shows a typical plot of lognormal probability density function for different values of its shape parameter σ . The corresponding plot for the hazard rate curves is shown in Fig. 7. The parameter μ is taken to be zero throughout since its basic role is to change the scale of the distribution on the time axis and not the shape of the distribution [1]. The moments and other properties of the distribution can be had from Ref. 15.

The inferential procedures for the model written in the (Eq. 12) are well understood from the standpoint of each of the major systems of statistical inferences, since by transforming to logarithms the problem can be reduced to the inferences from simple normal distribution and most of the procedures are routine. References 1 and 4 are the good references where classical procedures have been detailed for the lognormal distribution. Bayes procedures for the two-parameter model are given in Martz and Waller [10] using different prior combinations but most of the results directly follow from the normal distribution using the appropriate transformation. Needless to mention the fact that log lifetimes are normally distributed is often a convenience and is not much justified in the modern computing days.

Figure 6. Probability density function of the lognormal distribution when $\mu = 0$.

Figure 7. Hazard function for the lognormal distribution when $\mu = 0$.

The Generalized Gamma Distribution

The generalized gamma distribution is a fairly flexible three-parameter family that was first proposed in Ref. 18 and later on independently in Ref. 19. Its probability density function is given by

$$f(t | \alpha, \beta, \kappa) = \frac{\beta}{\Gamma(k)} \frac{t^{\beta\kappa-1}}{\alpha^{\beta\kappa}} \exp \left[- \left(\frac{t}{\alpha} \right)^\beta \right];$$

$$t > 0, \alpha > 0, \beta, \kappa > 0, \quad (15)$$

where α is the scale parameter and both β and κ determine the shape of the distribution. Sometimes $\beta\kappa$ is jointly referred to as the *power parameter*. As the name itself makes it obvious, this is a generalized family and includes as special cases all the important failure time distributions. Thus, it reduces to exponential distribution when both β and κ are set to unity. The Weibull distribution becomes a special case for $\kappa = 1$, and gamma as a special case for $\beta = 1$. In addition, the

lognormal distribution results as a limiting case when $\kappa \rightarrow \infty$. Like gamma distribution here also the survival and the hazard functions are not available in closed forms and involve the incomplete gamma integral. The expression for the survival function can be written as

$$S(t | \alpha, \beta, \kappa) = \frac{\Gamma(\kappa) - \Gamma(\kappa, (t/\alpha)^\beta)}{\Gamma(\kappa)}, \quad (16)$$

and the expression for the corresponding hazard function can be explicitly obtained using Equation (2).

Inferences for the generalized gamma distribution are even more complex due to involvement of additional shape parameter [1]. Much of the difficulties occurred because the usual classical techniques failed to produce any significant solution with the model written in form (15) mainly because of the complex nature of the corresponding likelihood function for any relevant sampling plan. Large sample methods are also found to be unsatisfactory because the limiting normal approximation approaches very slowly. An alternative reparameterized form of the model is given in Ref. 1 that simplifies matter to some extent but definitely does not offer the routine inferences. Bayes inferences are even more unmanageable for any prior-likelihood combination unless the work of Upadhyay and others [20] that appeared only recently (see also Ref. 13).

The distributions given above can be extended with an additional parameter λ known as the *threshold parameter* or the *guarantee time parameter*. The probability density functions can then be written by replacing t with $t - \lambda$ and the range of t then becomes from λ to ∞ , that is, no failure can occur prior to λ . Such models are typically nonregular and the inferences can be even daunting if the parameter λ is assumed to be unknown. Two-parameter exponential distribution may be an exception with regard to its inferential developments.

Other Continuous Distributions

Besides the above important models, there are several other continuous models that have received attention in a variety of

applications of failure time data analyses. Owing to space restriction, we shall not go into the details although a brief discussion supported with a very few important references will be provided for completeness. A few such models can be named as inverse Gaussian distribution [21], log-logistic distribution, Gompertz distribution, Gumbel distribution, Birnbaum–Saunders distribution, and Pareto distribution [1,4]. One can also consider a normal distribution either truncated on left at zero or defined in a way such that its negative region can have negligibly small probability.

Mann *et al.* [4] obtained a general time to failure distribution using a pure death process especially when a unit can suffer either a random or a wear-out failure. Models under the name of mixed or composite distributions have been discussed by several authors in order to allow more flexibility in fitting and explaining the failure data [1,4]. Models capable of representing bathtub and nonmonotone hazard shapes [22] have also been discussed exclusively although a practical difficulty is that these models are often quite difficult to handle statistically. A few models discussed above may be used for characterizing such hazard rate shapes [1] although there has been a practice in the recent years to generalize the existing models by introducing extra parameters so that they are capable of representing nonmonotone and bathtub hazard rate shapes [23].

Most of the models discussed above can be extended to include regressor variables resulting in what we call the regression models in failure time data analyses. Some specific models such as the proportional hazards [24] have been detailed in the literature and these received wide applicability in both the reliability and the survival analyses contexts [1]. Multivariate models in failure time data analysis have also been reported although not as elaborately discussed as the univariate models. The last category of models may arise, for example, in a situation where one can desire to model the joint failure time distribution of parts of an integral system consisting of several parts. Several other important situations for the use of

multivariate models are discussed in Ref. 25 among others.

A FEW COMMON DISCRETE FAILURE DISTRIBUTIONS

Discrete distributions are often used in the failure time data analyses when the random variables are available either in the form of categorical data or in the form of binary responses. Most of these distributions are fundamental statistical distributions in the sense that they have not been derived either using any physical processes or using any transformations on some directly or indirectly obtained random variables. A few such distributions include the geometric distribution, the binomial distribution, the negative binomial distribution, the hyper geometric distribution, the Poisson distribution, and the multinomial distribution, the last one can be considered to be a multivariate analog of the binomial distribution. Let us consider, for instance, a group of patients suffering from gall bladder diseases and one is willing to know the probability that how many of these have developed carcinoma. Obviously, binomial model can be a desired possibility. Similarly, consider a situation where a device is operating and every small period of the operation is identified as a trial. Thus, we may have trials, similar to Bernoulli, with failure-free operation or operation with failure. Suppose $X - 1$ is the number of successive periods of failure-free operation and X is the period at which failure occurs for the first time then X can be considered to have geometric distribution. The multinomial distribution arises, for example, when continuous data have been grouped in a number of classes and each class leads to certain frequencies. An example to this effect can be found in Ref. 1. Situations can be similarly noticed where binomial, Poisson, and other discrete distributions named above can be considered as appropriate distributions. References such as 1 and 4 can provide a few of such situations where these distributions may be important candidates. Reference 26 provides a detailed discussion of these distributions with several important properties.

COMMON RANDOM NUMBERS

LEE W. SCHRUBEN

Department of Industrial Engineering
and Operations Research, University
of California, Berkeley, California

COMMON RANDOM NUMBERS AND SIMULATION RUNS

Random phenomena are conventionally modeled in stochastic computer simulations and Monte Carlo experiments using transforms of one or more sequences (“streams”) of (pseudo)random numbers. Random numbers are regarded as observations of mutually independent and identically distributed uniform random variables strictly between 0 and 1.

A run of a stochastic model with feasible input factor values x transforms sets of random numbers U into samples of random variables or sample paths of stochastic processes $V(x)$, which are in turn transformed by the simulation code into random output data $Y(x)$. This output data is then used to compute estimators $\hat{\theta}(x)$ of interesting system characteristics $\theta(x)$, called the *simulation response* at x . A generic simulation run is

$$U \rightarrow V(x) \rightarrow Y(x) \rightarrow \hat{\theta}(x). \quad (1)$$

The fundamental idea of the variance reduction technique (VRT) of common random numbers (CRNs) is simply to reuse some or all of the random number streams to generate the same or different random processes for two or more runs that do not have identical inputs. U depends on x and the simulation run (1) becomes

$$U(x) \rightarrow V(x) \rightarrow Y(x) \rightarrow \hat{\theta}(x). \quad (2)$$

Some other VRTs including antithetic and control variates also fall within this framework and are collectively called *correlation*

induction methods. Of course, using the same streams to model *all* of the same random processes in two runs with the identical input factor settings, initializations, and durations will produce the same outputs. Something has to be different.

Representations (1) and (2) for a simulation run are abstract and general. Here we consider only simulation experiments in which *runs* are the observational units. (An example of a simulation experiment that is not run-oriented is a frequency domain screening experiment [1].) A simulation run involves more than merely choosing the input factor settings. For example, there are many important decisions that need to be made: how many replications should be run at a particular input setting; how a run should be initialized; how long it should be warmed up before collecting data; and when a run should be terminated [2]. No attempt is made here to address the many details that must be attended to when running a simulation.

The notion here of a simulation input factor is also abstract and general. Using a simulation, the experimenter conceptually can control and observe everything, depending on the flexibility of the simulation modeling software used. Unlike conventional experiments, a simulation input factor can be anything, which may or may not be controllable in the real-world system being modeled. For example, the distributions of random arrivals of customers and service times for a simulated queue are input factors that can be easily changed by the experimenter. In the real-world, these may be unknown and at best only partially controllable or observable. The numbers and types of servers are input factors for both simulations and real-world experiments. An experimenter using a simulation can fully control all inputs and even change them *during* a simulation run! Again, this power may be restricted somewhat by the simulation software. The simulation itself may actually be a collection of different computer programs that model identical, similar, or alternative systems, designs, and/or

operating policies. Thus different input factor settings may model very different systems with the same computer program, or they may model the same system using different simulation computer programs.

COMMON RANDOM NUMBERS AND SIMULATION EXPERIMENTS

At its most basic level, a good simulation experiment is designed and run to try to obtain estimators that have both low bias and low variance, and allows statistical assessment of the quality of the estimators. Designing a simulation experiment consists of carefully choosing sets of input factor settings, called *design points*. The experiment should be based on principles of statistical design of experiments (DOE) [3]. From a classical DOE viewpoint, the random number streams chosen for the runs in the experiment can be regarded as a nuisance factor. An experimental design can be blocked to remove the extraneous effects of random number streams. This can be done in an optimal manner to reduce the variances of interesting effects [4–7]. However, it can also complicate the analysis of the output [8–10].

Using standard DOE notation, the elements of the experimental design matrix X will have as its rows the values of scaled functions of the input factor settings for each design point. The factor settings in each run are the columns of X . The first column of X may all be 1's to include the mean effect in a regression meta-model that is to be fit to the output from the experiment. The setting for input factor i for simulation run j is denoted as $x_{i,j}$. (When there is a single subscript on x_i it will denote an experimental design point, input settings, at which there may be multiple simulation runs.)

When a simulation is run at input setting x_{ij} , $U_k(x_{ij})$ is any set of streams of random numbers that are sufficient to generate the random processes for the run. A more general definition of CRNs than typically found in the literature is running any simulation experiment where at least two streams are reused. We can use random number streams from the same sets of streams to generate some of the

same or different processes in the same or different runs at the same or different design points, as long as these are not *all* the same (which would produce identical output).

Definition : $CRN \Leftrightarrow \exists k, k', i, j, i', j' :$

$$\begin{aligned} U_k(x_{ij}) \cap U_{k'}(x_{i'j'}) &\neq \emptyset \\ \forall k \neq k' \vee i \neq i' \vee j \neq j' \end{aligned} \quad (3)$$

We can use any subset of random number streams in different, or the same, runs even if they are at the same design point as long as they are not used to generate all the same random processes. This broader definition also includes antithetic and control variate VRTs and includes interesting variations like that in Refs 8, 11 and 12.

The intuition behind the CRN simulation strategy is the same as for any real laboratory experiment that compares two or more systems. Simply, subject the tests of the different systems to common sources of extraneous randomness that otherwise merely contaminates the measurements. That is, try to observe the different systems in the same controlled environments. There is some sound theory behind this practice, which at times has been misinterpreted. The most straightforward result is the fact that when the variance of the difference between the response estimators for two different systems $D(x_i, x_j) = \hat{\theta}(x_i) - \hat{\theta}(x_j)$ is

$$\begin{aligned} \text{Var}[D(x_i, x_j)] &= \text{Var}[D(x_j, x_i)] = \text{Var}[\hat{\theta}_i - \hat{\theta}_j] \\ &= \text{Var}[\hat{\theta}_i] + \text{Var}[\hat{\theta}_j] - 2\text{Cov}[\hat{\theta}_i, \hat{\theta}_j] \\ &= \frac{\text{Std}[\hat{\theta}_j]}{\text{Std}[\hat{\theta}_j]} + \frac{\text{Std}[\hat{\theta}_i]}{\text{Std}[\hat{\theta}_j]} - 2\text{Corr}[\hat{\theta}_i, \hat{\theta}_j]. \end{aligned} \quad (4)$$

When the two system responses are run using independent (disjoint sets) of random number streams, the correlation is zero. But, if CRN is used, *and* this results in $\text{Corr}[\hat{\theta}(x_i), \hat{\theta}(x_j)] > 0$, then the variance of their difference is reduced from its value for independent sampling by twice the estimator covariance. CRNs are perfectly correlated ($\text{Corr} = 1$). Since using CRNs do not induce a bias in the response, the hope is that when CRN streams are used, then the estimated responses will still have significant positive

correlation after the sequence of transformations in Equation (1). Unfortunately, this is sometimes not the case, particularly when the systems are far apart according to some metric on the x 's.

CRN Synchronization

A loss in induced correlation magnitude occurs when simulation runs require different numbers of random numbers, and the input random number streams get out of synchronization. Then the same random numbers may be used to model different random processes in the different simulated systems. For example, in comparing two simple simulated queueing systems—like Example 11.1 in the textbook given in Ref. 2—it may be that the same random number that was used to generate a time between customer arrivals in one system is used to generate a service time in the other simulation. These two random variables have opposite effects on the level of congestion (shorter service times result in smaller lines, and shorter times between customer arrivals result in longer lines). Blindly using CRNs hoping to highlight the differences in these systems might be detrimental, resulting in increased variance of the estimator for the differences in performance between the systems—ultimately resulting in a lower probability of being able to identify the better system.

There are several suggestions for improving the chances of inducing positive correlations in simulation estimators. The simplest is to use the same streams to generate the same stochastic processes in runs of different systems [2]. For example, the same stream used to generate the arrivals in one queueing system is used to generate the arrivals in the other system. A different set of streams is reused to generate the service times for both systems. In general, distinct random number streams can be used to simulate components or processes in the simulation models that are identical or closely related, and independent streams (re)used to generate processes that are very different. Table 11.3 on page 587 in Ref. 2 demonstrates that using one stream of random numbers

to generate customer arrivals and a separate stream to generate service times when comparing two queueing systems effectively reduces the variance of the differences in their estimated performance. The result is a significant improvement in the ability to identify the better of two competitive systems. (This experiment was replicated as a homework problem producing similar, but notably less dramatic, results.)

However, in all but the simplest models, it is not easy to keep random number streams synchronized across simulation runs. We will see there is a simpler approach later.

Simulation Experiments

A common goal for a simulation experiment is to fit an additive noise regression meta-model to the response

$$Y = X\theta + \varepsilon(X), \quad (5)$$

where ε is some random noise in the output. There are many alternative, more sophisticated, meta-models and simulation study objectives.

When estimating the average (or equivalently the sum) of two responses for the same or different systems, the positive correlation induced by using CRNs will *increase* the variance since the sign of last term in the variance of the sum, corresponding to Equation (4), would be positive.

Therefore it is important to know what effects in x are of interest. To illustrate, consider the simple case where we are interested in estimating the coefficients of a homoscedastic (constant variance) linear additive-noise response meta-model to a one-dimensional input factor. A simple model is given by

$$Y(x) = \theta_0 + \theta_1 x + \varepsilon(\sigma). \quad (6)$$

Here the system response estimator is three dimensional: the mean effect or intercept $\hat{\theta}_0$, the main effect or slope $\hat{\theta}_1$, and the noise standard deviation $\hat{\sigma}$. We will assume that the noise can be estimated from the pooled outputs from the runs using, for example, standardized time series or batched means [2]. Therefore, we make only

Figure 1. Three possible experiments to fit response model (6) using CRNs and antithetic CRNs (b).

two runs, one at a low value of x and one at a high value of x , which are scaled to be $x_1 = -1$ and $x_2 = +1$. We run the simulation and get the outputs $Y(x_1)$ and $Y(x_2)$. We will denote the common variances of these outputs as σ^2 and the *magnitude* of their correlation (if any) by ρ .

The ordinary least squares (we are assuming that the noise is not dependent on x) estimators are

$$\hat{\theta}_0 = \frac{1}{2}[Y(x_1) + Y(x_2)] = (.5, .5) \begin{pmatrix} Y(x_1) \\ Y(x_2) \end{pmatrix} \quad (7)$$

and

$$\hat{\theta}_1 = \frac{1}{2}[Y(x_1) - Y(x_2)] = (.5, -.5) \begin{pmatrix} Y(x_1) \\ Y(x_2) \end{pmatrix}.$$

The variances of these unbiased estimators are given by

$$\text{Var}[\hat{\theta}_0] = \frac{\sigma^2}{2}(1 + \rho) \quad (8)$$

and

$$\text{Var}[\hat{\theta}_1] = \frac{\sigma^2}{2}(1 - \rho).$$

We see that successful CRNs ($\rho > 0$) reduce the variance of the estimator of the slope but *increase* the estimator of the intercept by *exactly the same amount*. There is no overall net gain in variance reduction by inducing correlations. This is one reason that correlation induction has sometimes been called a *Monte Carlo swindle*. Using antithetic CRNs (where CRNs are subtracted from 1 before use) to try to induce negative correlations in outputs from the two runs has the opposite effect. The variance of the intercept is reduced, but the variance of the slope is increased by the exactly same amount; so, again, there is no net gain in variance reduction.

Intuitively, we can visualize the Monte Carlo swindle going on here in several ways. Figure 1 shows three possible independent outcomes of experiments to estimate the response model given by Equation (6). In the left frame of Fig. 1, a successful application of CRNs was used for each pair of runs in the three different experiments. We see that the pairs of values of the outputs Y for each experiment tend to occur in the same tails of their respective distributions. This results in low observed variability in the three estimated slopes, but high variability in the three intercepts.

In Fig. 1b, *antithetic* CRNs (where each random number is subtracted from 1 before use) were successfully applied so that values of Y tend to occur in the opposite tails of their respective distributions. This results in low variability in the three estimated intercepts, but high variability in the three estimated slopes.

Using the vector inner product representations of the estimators in (7), we can view the estimators $\hat{\theta}_0$ and $\hat{\theta}_1$ for this model geometrically as the lengths of the projections of the output vector $(Y(x_1), Y(x_2))$ onto the lines in the $(0.5, 0.5)$ and $(0.5, -0.5)$ directions. Figure 2 shows an ellipsoid of concentration (proportional to contours of the distribution) of the output vector if these are assumed normal with positive correlations.

Increasing positive correlation causes these contours to become more and more elliptical with a 45° slope for the major axis (this slope is 45° because of the equal estimator variances). The longer possible lengths of the projections of the output vector on the $(0.5, 0.5)$ line cause variation in the average or intercept estimator $\hat{\theta}_0$. The positive correlations in the outputs simultaneously make the lengths of the possible projections of the output vector on the $(0.5, -0.5)$ line,

Figure 2. Elliptical contours of the output distributions with positive correlation.

that is, the slope $\hat{\theta}_1$, shorter, resulting in smaller sample variances. If the outputs were negatively correlated, the major axis of the contours would have a -45° slope with the opposite effects on the variability of $\hat{\theta}_0$ and $\hat{\theta}_1$. Figure 2 is complicated, but it is worth studying carefully.

Next consider a system with two input factors where we wish to estimate the meta-model

$$Y(x) = \theta_0 + \theta_1 x_1 + \theta_2 x_2 + \varepsilon(\sigma) \quad (9)$$

using a 2^2 full factorial design [3] running two low and two high values of each factor. The design is pictured in Fig. 3, where the same set of CRNs are used in all four runs but their antithetic sets are used in the two orthogonal fractional designs (at opposite corners).

Using the same notation as before, we find that the least square estimator variances are now given by

$$\begin{aligned} \text{Var}[\hat{\theta}_0] &= \frac{1}{4}\sigma^2(1 - \rho) \\ \text{Var}[\hat{\theta}_1] &= \frac{1}{4}\sigma^2(1 - \rho) \\ \text{Var}[\hat{\theta}_2] &= \frac{1}{4}\sigma^2(1 - \rho). \end{aligned} \quad (10)$$

This time, the variances of *all three* estimators are reduced. There appears to be no Monte Carlo swindle. The missing variance

Figure 3. A 2^2 factorial design with common and antithetic $1/2$ fractional blocks.

can be found by considering another possible meta-model that saturates (having the same number of unknown θ s as runs) the experimental design. This model adds an interaction effect between the two factors:

$$Y(x) = \theta_0 + \theta_1 x_1 + \theta_2 x_2 + \theta_{12} x_1 x_2 + \varepsilon(\sigma). \quad (11)$$

The variances of the least squares estimators for this model are

$$\begin{aligned} \text{Var}[\hat{\theta}_0] &= \frac{1}{4}\sigma^2(1 - \rho) \\ \text{Var}[\hat{\theta}_1] &= \frac{1}{4}\sigma^2(1 - \rho) \\ \text{Var}[\hat{\theta}_2] &= \frac{1}{4}\sigma^2(1 - \rho) \\ \text{Var}[\hat{\theta}_{12}] &= \frac{1}{4}\sigma^2(1 + 3\rho) \end{aligned} \quad (12)$$

The Monte Carlo swindle is back: all of the variance that was taken from the first three estimators in the additive meta-model is in the variance of the interaction estimator. So, considering the saturating meta-model, the there is no net variance reduction.

These observations are more general: For saturated orthogonal experimental designs, the sum of the variances of the independently estimable parameters is a constant equal to the sum of the variances of the observations, regardless of the correlations. This is sometimes called the *total variance* in $(\hat{\theta}_0, \hat{\theta}_1)$ and is the sum of the eigenvalues of its dispersion matrix. The Monte Carlo swindle is a result of the fact that saturating an orthogonal experimental design makes the design matrix X square (the number of estimators and the number of runs n are equal). Therefore, because the rows are also orthogonal

$$XX' = X'X = nI_n. \quad (13)$$

Here I_n is the identity matrix. Let D denote the variance-covariance matrix of the simulation outputs (the $Y(x_i)$'s). Let C denote the variance-covariance matrix of all parameter estimators (the $\hat{\theta}_i$'s). Then the trace, $\text{Tr}[C]$, is the sum of the variances of the estimators. For generalized least squares (also for ordinary least squares when the result in Ref. 13 applies)

$$\begin{aligned} \text{Tr}[C] &= \text{Tr}[(X'D^{-1}X)^{-1}] = 1/n \text{Tr}[D] \\ &= 1/n \sum_{j=1}^n \sigma_j^2. \end{aligned} \quad (14)$$

where σ_j^2 is the variance of the output from the j th run, $Y(x_{ij})$.

Thus the sum of the variances of the estimators computed from the simulation experiment will be equal to the sum of the variances of the outputs from the simulation runs, regardless of their induced correlations. One can induce correlations between the simulation outputs to reallocate the estimator variances to uninteresting estimators (like the interaction term in model (8), but this will not reduce the total variance.

The only possible benefit to using CRN in such situations is if there is a factor, like the

interaction term in model (8), that we are willing to assume is zero or at least of much less important than the other effects. We can then deploy CRNs and their antithetic sets to simply maximize the variance of this unimportant estimator [14].

An obvious strategy then is to add enough uninteresting effects to a meta-model in order to saturate an orthogonal experimental design. Then assign the correlations to maximize the sum of their variances, thus shifting variance away from interesting estimators. This is a more general and simpler strategy for applying CRNs than those in the references and includes many of the optimal rules as special cases.

COMMON RANDOM VARIABLES

When full CRN simulations are run, $U_{ijk} = U_{nmk} \forall x_j \neq x_m$, the random numbers are identical and hence have a perfect correlation of +1 (antithetic CRN streams have perfect negative correlation of -1). When these random numbers are filtered through a simulation run abstracted by Equation (2), the outputs inevitably lose some of this correlation, (unless, say, all the transformations are linear).

A major reason for loss of correlation in simulation outputs comes during the transformation from the uniform random number streams into random variables ($U \rightarrow V$). The maximal correlation between two random variates is obtained by using the inverse CDF transforms with the same random number, $(x, y) = (F_X^{-1}(u), F_Y^{-1}(u))$, which is typically not linear unless uniform random variates are being generated by shifting and/or scaling the random numbers [15]. Furthermore, for the most interesting random variates, these inverse distribution functions need to be approximated and there are faster and exact generation algorithms. Except for a few special random variable generation algorithms, more than one random number is needed for each random variable. For example, in an acceptance/rejection algorithm for generating random variables, a random number of random numbers is used to generate each random variable [2].

Using the general definition of CRNs in Equation (3), it is possible to improve the correlation between generated random variables using acceptance/rejection. For example, one stream of random numbers can be used to nominate values of a random variable and another can be used to test against the acceptance level. The two streams can be easily synchronized at every initiation of algorithm for generating correlated pair variates by discarding unused variates in the shorter stream (corresponding to the streams used to generate the beta variate that needed the fewer streams). An alternative is reported in Ref. 16.

To illustrate this idea, consider generating beta random variables using an acceptance/rejection algorithm. The beta is a popular random variable choice for stochastic simulation since it can take on a wide variety of shapes useful for sensitivity analysis. Some examples of beta variate shapes, controlled by two shape parameters, are given in Fig. 4.

Since the number of random numbers used to generate each beta variate is random, it is very hard to generate correlated

beta variates unless they have the identical shapes and differ at most by a linear transformation (then they are perfectly correlated). When the distributions have even slightly different shapes, the observed correlation between pairs of beta variates using CRNs is essentially not increased if at all. In an experiment, the estimated correlations between 10,000 CRN pairs of betas with the different shapes in Fig. 4 were rarely outside the range from -0.01 to +0.01, with the largest positive correlation only 0.07, essentially zero [16].

To improve the correlation between pairs of random variables, one stream is used to nominate values and the other for testing acceptance. When the betas have the same shape, the generated values are, of course, the same. However, when their shapes are different, the induced correlation degrades only marginally. Table 1 (also from Ref. 16) shows the estimated correlations between 10,000 pairs of beta random variables with the different shapes in Fig. 4. There is a dramatic improvement over the lack of correlations found using straightforward CRNs.

Figure 4. Beta random variates with different shape parameters [17].

This method of generating correlated betas was used in the example mentioned earlier in Ref. 2. For this problem, the service times of the faster servers (called *zippy* in Ref. 2) are distributed as $(9/4) \times \text{beta}(2,3)$. This distribution has a mean of 0.9 and a range of $(0,9/4)$. The service times of each of the slower system servers (called *klunky* in Ref. 2) are distributed $3 \times \text{beta}(3,2)$. This distribution has a mean of 1.8 and a range of $(0,3)$. The induced correlations between the system performance estimates increased from essentially zero (-0.04) for independent streams to 0.93, resulting in the estimated variance of the difference in performance being reduced from 7.41 to only 0.41 [16].

The use of one set of streams of random numbers to nominate values and another set to test acceptance can be generalized to Metropolis–Hastings Markov Chain Monte Carlo sampling [18].

COMMON RANDOM MODELING

Some of the difficulties in generating correlated random variables and synchronizing input processes can be avoided by using common modeling components. To illustrate this, we again use the example cited earlier—Example 11.1 in Ref. 2—where the performances of two simple queueing systems are compared. The simple event relationship graph (ERG) model on page 47 in Ref. 2 can be used to model both systems, and is shown explicitly in Fig. 5, where R is the number of servers and the simulation output is the Q process—the number of jobs in the system. Here, t_a represents the random times between job arrivals, and t_s represents the random service times. Conditions (/) required for event scheduling and delay times between scheduled events are shown in Fig. 5, making this a complete model.

The two events in this ERG model merely increment and decrement the Q when jobs ENTER the system and LEAVE the system. (This same ERG model can model waiting times, batch arrivals and processing, service breakdowns and repairs, etc. [17,19] with different event state changes.)

Figure 5. An event relationship graph (ERG) model for a G/G/R queue.

Figure 6. A Single ERG model for two queueing systems with identical arrivals.

Reading the dynamics in an ERG is easily done by interpreting each arc in a single sentence. Hence the complete dynamics for this model requires at most three sentences to define. The dynamics in the ERG is given by a single sentence for each of the three arcs:

1. Unconditionally a new job will ENTER ($Q++$) the system every t_a time units.
2. When a job ENTERs the system and finds an idle server ($Q \leq R$), it does not have to wait and can LEAVE ($Q--$) after its service time of t_s .
3. When a job LEAVES, if there still jobs waiting ($Q \geq R$), the next job will be served and can LEAVE after its service time of t_s .

To create perfectly correlated job arrival times for the two different service systems, like for the example mentioned earlier from Ref. 2, the two simulated systems can be combined into the single ERG in Fig. 6, with arc labels not displayed.

In the ERG model in Fig. 6, the two share the same ENTER event, which increments the Q for both systems. The induced correlation between job arrivals is perfect since they are identical. Service times can be generated and synchronized using some of the methods mentioned earlier in this article. The concept of a single model of several systems can be extended and exploited in many more ways as discussed in Ref. 18. Sharing common modeling components in an ERG model allows CRN to be used even when the seeds for the random number streams are not easily repeatable (like RAND() in Excel). This is a partial answer to the problem at the top of page 580 in Ref. 2: "...irreproducible gimmicks ... would generally preclude the use of CRN as well as many other valuable VRTs."

FURTHER READING

CRNs are by far the most commonly used and researched VRT (the full title of this article had over 50 000 Google references when it was initially published). Significant research papers that show the remarkable breadth and depth of CRN research spanning over a quarter century include Refs 20–23.

COMMUNICATING DECISION INFORMATION TO THE LAY RISK MANAGER: A CONSULTANT'S PERSPECTIVE

REX BROWN
School of Public Policy, George
Mason University, Fairfax,
Virginia

OBJECTIVES

A risk manager often finds he¹ has difficulty using information to form his own judgment or to explain it to others. He may not use it effectively—if at all. In this article, I suggest how an information provider can adapt the form and content of a communication to serve a risk manager.

The purpose may be to help him to choose among identified options (now or in the future), or to decide what new information to seek first. The purpose may also be to justify his action, before or after the fact.

Writer's Perspective

My treatment is selective and personal (and sometimes controversial). This is not intended as a balanced report of the state-of-the-art of information communication

My perspective is based on 50 years of consulting, mainly to government risk managers [1], often at the highest levels.² This experience covers a broad spectrum

¹Throughout this article, “he” means “he” or “she.”

²Including office heads at the Nuclear Regulatory Commission and the Department of Energy, an Assistant Secretary of Defense, a Deputy Assistant Administrator of EPA, a US Senate Committee, a House representative, and midlevel officials at IAEA, federal aviation administration (FAA), Corps of Engineers, and the Department of Commerce.

of risk management situations.³ My work with business executives,⁴ though not generally on risk management, has been quite relevant. The perspective is also based on two research projects, one for NSF⁵ to develop communication methodology, the other for NRC⁶ to test it in practice [3,4]. My technical approach has been lately applied decision theory (ADT) [5].

Elements of the Communication Process

The communication process has several roles. A Provider of information, P (e.g., a risk analysis contractor) produces Data, D (e.g., prescriptive decision analyses, factual risk assessments, value judgments, raw data, personal judgment or observation), and turns it into a Communication, C (e.g., a report or an interactive process). A Translator, T (e.g., decision analyst, who may also be the Provider, P) transmits it to a Risk manager, R (e.g., an executive, legislator or regulator), who is taking some Action, A (e.g., a safety intervention or research activity).

An Illustrative Case: Reactor Safety

A past consulting case will illustrate much of the argument. A senior nuclear regulator R was deciding whether to close down a reactor he suspected was unsafe, or to require

³Including reactor safety, waste disposal, air quality, airline security, business fraud, civil engineering construction, emergency planning, health risk, nuclear proliferation, laboratory accidents, anticrime legislation, gasoline additives, nuclear safeguards, military crisis management, submarine warfare, telecommunications emergencies, and toxic substance control [2].

⁴Including presidents and vice presidents at Ford, Firestone, Perkins Engines, and smaller companies.

⁶Division of Risk Analysis and Operations.

major safety backfit measures, or to do more research first A.

He had received a classic probabilistic risk assessment D, for which the reactor operator had hired a contractor at a cost of \$4 million. The PRA indicated that the reactor was among the safest in the United States. However, R knew of enough accident near misses at the reactor to put it on a warning “watch list”. Although technically sophisticated, R had difficulty extracting from the PRA what he needed to form his own judgment or to justify it, if it were challenged. The PRA also indicated that a “venting backfit” would be the most cost-effective backfit and R found *that* convincing.

My colleagues and I, T, worked with R a few weeks on evaluating the PRA and combining it with other available information, including R’s own observations and the informed judgment of colleagues [6,7]. In the light of this more comprehensive analysis, R decided to permit the reactor to operate, subject to a venting backfit. We developed a report and interactive software C designed to defend the decision if it were challenged, but it was not.

ASSESSING RISK

The Substance: Subjective versus “Objective”

A judgment-avoidance culture is common among information providers P who purport to limit themselves to “objective” information, disregarding critical “soft” information D. This objectivity orientation is legitimate in scientific enquiry, but some of us [8] hold that it does not belong in analysis intended to aid decisions and may seriously distort action. It often leads to analyses embodying simplistic “cop-out” assumptions that imply unrealistic personal judgments.

For example, a proposed regulation is often evaluated *as if* the regulated party were certain to faithfully implement requirements—which is rarely realistic. This has the effect of overvaluing the regulation, since it may be less effective than was assumed. By how much, is the question for informed judgment (but it will not matter too much if

it simply strengthens a case for rejecting the regulation).

Simplified assumptions need not invalidate a communication C provided they are recognized and translator T helps R to make appropriate adjustments to his judgment.

A very common and reasonable simplification is to treat an incremental decision strategy (like putting your toe in the water before taking the plunge) as if it were a once-and-for-all commitment (like plunging without hesitation). The simplification *undervalues* the incremental strategy [since R can retreat if the water is too cold]. A risk management example would be the case where there are signs of an impending reactor accident. The operator R has to decide whether to begin shutting the reactor down, given that he can abort the shutdown if it proves to be a false alarm. He can evaluate the incremental shutdown step *as if* it committed R to shut down irrevocably, and use his informed judgment to adjust the evaluation upward.

A prime example of a judgment-avoiding assumption is classic PRA, referred to in the reactor backfit case. Such PRAs, as prescribed in regulatory guidelines [9], normally address only sources of risk with well-documented evidence (say from experiments or testing) and disregard other evidence (such as unplanned observation).⁷

In the reactor case, the PRA addressed only internally initiated core melt accidents (such as pipe breaks) and ignored external accidents (such as station blackout), as sources of risk (as well as any *informal* evidence about internal accidents). From other sources we sought probabilities of externally initiated events. On the basis of this adjustment, R rejected the PRA finding that the reactor was adequately safe overall and required that a costly backfit be installed A.

The PRA may contain a great deal of relevant information (as in this example), but is not sufficient on its own, to produce a realistic risk assessment. Experienced regulators let PRA guide them in certain cases, such as engineering design, where there is, in fact,

⁷“PRA” might be interpreted as “Partial Reliability Assessment.”

authoritative evidence on all relevant sources of risk and virtually no other useful evidence. In the reactor case, R accepted the PRA finding that a venting backfit was preferred to an alternative, since the PRA omissions did not affect that comparison.

Special Cases

“Unknown Unknowns”⁸. The Code of Federal Regulations [10] requires that “the likelihood” (see section below titled “The Form”) that a certain total radioactive emission level from a waste repository over 10,000 years should not exceed 10%. A DOE study of the proposed Yucca Mountain site found the human intrusion component of that likelihood to be of the order of one in a million. This assumed that the only source of human intrusion was mining for minerals—the only source that the authors could identify. (This would be like the Indians on Manhattan Island 10,000 years ago assuming that the only risk of human intrusion into a sacred burial site by 2000 AD would be the robbery of ancestral bones. . .)

In view of the hopelessness of coming up with a defensible and realistic probability of unvisualized human intrusion, I suggested reformulating the risk of a site along the lines of “the probability of any presently identifiable human intrusion that *differentiates among* contending nuclear waste sites.” In other words, report only risk information *relevant to the decision purpose at hand*. In this case, report only whether the presence of mineral deposits at Yucca Mountain makes it more or less susceptible to human intrusion than contending waste sites. If other sources of intrusion cannot be specified (i.e., unknown unknowns), they cannot affect the current *comparison* of sites, and can be safely ignored.

Sample Data. Sample data, say, of public risk attitudes and system failures, are particularly vulnerable to miscommunication due

to judgment-avoidance culture. Errors, that is, differences between the sample as measured and the population of interest, can arise from a number of causes. Usually only one of them, random sampling fluctuations, can be “objectively” reported. Established statistical procedure can produce a random sampling error, but that is commonly cited as the whole “margin of error.” This is appropriate in those cases where the sample is indeed drawn randomly from a stable repetitive process of interest and can be accurately measured. In the manufacture of standardized mechanical components, the sample may come close enough for the “random sampling error” to be almost all total error.

However, in many important cases, sources of error other than random are much greater. Suppose R wishes to assess what fraction of the US population engages in some risky practice (such as phoning while driving). In a large random phone sample from the DC directory, 5%, say, admit that they have done so in the past week. This 5% is reported to R with a statistically calculated “90% margin of error of, say, $\pm 1\%$ ” that is, 4–6%. R’s realistic uncertainty range could well be, say, 10–40% if R takes account of uncertain biases, because people can be expected to understate their dangerous behavior and/or DC phone subscribers differ from the US population. It is legitimate for P to communicate $\pm 1\%$ as the purely random component of total error and alert R to other errors he must take into account. Alternatively, he can help R to quantify those errors. A *calibration sample*, where the actual behavior of a small subsample is meticulously observed, can introduce some degree of objectivity [11].

Rare Events. Comparing very low probabilities is difficult, but may be critical (e.g., when deciding how much it is worth spending to reduce the risk of a nuclear accident). Equating the probability to an analogy that R is likely to be familiar with (e.g., being killed in a car accident; or 10 heads in a row; or being struck by lightning; or a royal flush, for a card-player) may better convey appropriate uncertainty [12]. Familiar analogs can also be used to convey quantities that are

⁸“There are more things in heaven and earth, Horatio, than are dream’d of in your philosophy”—Hamlet.

mind-bogglingly *large* (e.g., noting that a \$300 billion borrowed from China to make infrastructure safer is equivalent to \$1000 more debt for every US citizen).

The Form

Language for the Layman. Language is an essential component of communication strategy. Misleading or confusing language on its own can—and often does—doom a decision-aiding effort.

I was much chastened by an early career experience. I presented a company president with an analysis of a major decision, couched in conventional technical language. Before I finished, he grunted “gobbledygook!,” stormed out of the room and never sought my help again! Many a decider has been lost to analysis because he had not the time, the patience, or the training to absorb what he was hearing.

I will not enter, here, into the current debate in the decision-aiding literature⁹ on reforming decision vocabulary. Instead, I will adopt existing conventions, which are acceptable when engaging a technical audience. However, I will mention, in passing, a few lay translations, which have helped me avoid confusing and misleading laymen. In particular, I will replace “decision analysis” with the more specific “applied decision theory” [15]. Using “frequency” to characterize what decision analysts call “probability” is meaningless if R’s personal judgment is what is being aided (unless some real iterative process is involved, such as component failure).

Where possible I follow some respected vocabulary precedent.¹⁰ Hopefully, an authoritative professional body will, in time, authorize a standard glossary¹¹ that we can

confidently use when communicating with lay deciders.¹²

Graphical devices for getting across simple uncertainty, expressed in terms of R’s personal probability, have been well addressed at some length by other authors [17]. Devices include various variants of bar charts that show means and credible intervals and probability density curves. (Laymen appear to find cumulative curves more difficult to interpret).

EVOLVING COMMUNICATION FOR PRIVATE DECISION MAKING

Communicating risk management information for R’s private decision making can have two distinct phases: basic and interactive. In the “basic phase,” the communicator identifies a minimum set of information that R will certainly want to know, and which P can prepare ahead of time. This usually takes the form of a basic report, which is typically a written document or a formal briefing. The “interactive phase,” conveys optional information in response to R’s interest that emerges later. This is what I will now discuss.

The Macromodel as an Organizing Device

I have found the “macro model” to be a convenient vehicle for conveying an evolving decision argument in the interactive phase. This is a structurally simple model of a “target” judgment, an extreme example of which would be “net value of option = benefit—cost.”¹³

Any macromodel input can be derived by plural evaluation, that is, making an assessment in several ways and merging possibly inconsistent results. Each component assessment may include R’s intuitive judgment

⁹See Ref. 13 and discussion in Decision Analysis, June 1994, and my tentative proposal in Ref. 14.

¹⁰For example, I adopt Schlaifer’s replacing of “utility” by “preference” to connote its personal nature [16], and accept Howard’s rejection of “expected” implying unnecessary confidence [12]. I tentatively suggest “projected preference” in place of “expected utility”.

¹¹As the Academie Francaise does for the French language.

¹²As well as students—and perhaps, eventually technical specialists.

¹³Where the target is a probability (e.g., of accidental damage), the macromodel could be an inference equation. Its inputs would be unconditional probabilities of conditioning events (such as types of accidents) and the conditional probabilities of damage in each case. They would be combined in a familiar conditioned assessment formula.

Table 1. Macromodel for venting backfit of option

	Baseline	Backfit Impact
<i>Inputs</i>		
Factual judgments		
Core melt/year probability ($\times 1\text{E}-4$)	0.76	0.63
Conditional off-site radiation (man-rem)	23.7	0.6
Off-site damage (\$B)	1.7	0.6
On-site damage (\$B)	4.6	1.0
Industry backfit cost (\$M)	4.8	
Regulator cost (\$M)	0.3	
Plant life (years)	30	
Value judgments		
Radiation—cost trade-off (man-rem)	1000	
<i>Outputs</i>		
Total benefit	\$40.6 M	
Total cost	\$5.1 M	
<i>Net benefit of venting</i>	<i>\$35.5 M</i>	

and the output of “feeder” models or studies, which are then combined.

Table 1 refers to a macromodel we used for the reactor backfit case. It shows estimates for the venting backfit option, resulting in a positive net benefit of \$35.5 M, compared with “do nothing.” An alternative backfit, showed a negative net benefit of \$24.8 M. The uncertainty ranges assessed (not shown here) implied a 90% range for net benefit of \$13.4 M–\$159.6 M¹⁴ R took this into account when deciding to require the venting backfit.

It included an assessment of a core melt accident within the next year with a probability of 0.000076, and a mean estimate of 23.7 man-rem of emitted radiation, which is a determinant of resulting deaths. These numbers drop to 0.000063 and 0.06 man-rem, respectively, with a venting backfit. They also included judgmental adjustments for omissions and biases (see section titled “The Substance: Subjective versus Objective”).

Another project [18] evaluated the cost effectiveness of the Clean Air Act. Inputs to a macromodel included industry costs and impact on various classes of pollution, supplied by specialized contractors (e.g., the US Geologic Survey). However, the contractors

did not report their findings in the form required as input to our macromodel, and “bridging” analyses were needed. The need for bridging analyses slowed down presentation to the Democratic Congress, which had mandated the study, until it was replaced by a Republican Congress, which cancelled the study!

The Interactive Phase

Figure 1 illustrates the role of a macro model in mediating between a target judgment and various sources and levels of input judgment, analysis, and data. It shows schematically the kinds of considerations R took into account, including plural evaluations for each element.

In the reactor case, we presented R with an interactive computer graphic display of a macromodel corresponding to Fig. 1, augmented by input uncertainty ranges. The input values included those shown in Table 1, derived from our digestion of the PRA and whatever other information was available. Each assessment was extracted and second-guessed from various kinds of data (e.g., elements of PRA and ADT analyses, experimental or anecdotal observations, and engineering and health statistics).

R worked with the display, overriding inputs as he saw fit, either from his direct judgment or by referring to other sources

¹⁴The combining formulas were familiar statistics decompositions.

Figure 1. Macromodeling of backfit net benefit.

of data, and noting the resulting impact on the backfit net benefit display. In this way, R dynamically probed deeper and deeper into the available information mass, as need dictated. On the basis of such progressive iterations, he made his final judgment: to require the venting backfit.

Contingent Decision Aid

Sometimes a decision tool is designed for future contingencies. The as-yet-unknown circumstances are inputted to the model structure when the situation arises.

Lab Accident Example. The EPA had our team [19] develop decision aid for chemical laboratory directors R to determine what level of risk control to apply to hazardous chemical operations (e.g., simple lab bench precautions vs. full containment equipment).

A team of chemical engineers had constructed a large generic risk, intended to apply to any lab experiment. It calculated overall probabilities of accidental injury as output of a single complex micromodel, with over 1000 variables (such as features of the experiment and properties of the materials involved). We structured the model as a hierarchy of macromodels whose inputs R could override at any level of aggregation.

For example, in a midlevel macromodel, the micromodel calculated the probability of

a spill in a certain experimental situation as 1%. However, one R noted that in the past 30 experiments there had been three spills, that is, 10%. After conferring with colleagues experienced in comparable situations, R substituted 5% for the 1% as input to the corresponding macromodel. He similarly overrode other variables in the macromodel hierarchy, and accepted as his own risk assessment the output of the top-level macromodel.

COMMUNICATING WITH OUTSIDE PARTIES

The Need to Justify Action

Guidelines for communicating with risk managers generally also apply to other areas of business and government where uncertainty is significant.

However, a distinguishing feature of risk management is that decisions are often controversial and need to be justified, for example, to the public or the courts. In our reactor case, a decision to close down a plant operation or require expensive safety measure is liable to be challenged. R may have good grounds for his choice, but not be able to demonstrate uncontroversially that it is sound, which requires documented evidence (such as engineering tests).

Although businesses have lesser need for a defensible rationale than government, a significant exception is the case of

legal “prudence hearings.” To avoid often crushingly expensive liability, a company may need to defend itself against a charge that it made “imprudent” decisions resulting in major environmental damage, perhaps requiring government superfunding to cleanup.

Criteria for Communication

Like decision rationale for R’s *private* use, a rationale for *public* use must be readily and quickly absorbed. However, it must also be “acceptable” to the audience. In particular, the *apparent* role of subjective judgment must be minimized. Thus, even if a regulator’s decision to, say, close down a reactor were based, largely, on his personal observation of lax safety practices, he would be well-advised to cite just one formal decision analysis that supported the same decision. (If he has reconciled all plural evaluations, they all will point to the same choice.) Some legal experts [20], but not others [21], hold that a decision produced by some systematic process (like ADT) is valid defense against being considered “arbitrary and capricious.”

Value Judgments

A risk management decision depends on typically very subjective value judgments, which can be difficult to validate and are politically sensitive.

Legislators shy away from putting a dollar value on human life, although they do so implicitly whenever they pass legislation intended to save lives. A congressman told me that if he proposed any value of a human life (regardless of what it was), it would incite hostile and emotional public reactions and lose him votes.

In the reactor backfit case, risk could be evaluated in two ways, according to different versions of published regulation [22]. Radiation harm can be evaluated at \$1000 per man-rem, or at \$20 million per life (which are cited in regulations). As shown in Table 1, we opted for the former as less provocative (if less relevant).

Where R has private interests beyond public welfare, he may prefer not to disclose embarrassing value judgments. A nuclear

regulator may, for example, be inclined to make safety requirements stricter than meeting health rules require, in order to avoid the bureaucratic hassle and political outcry of, say, the 1979 Three Mile Island accident. In the backfit case including “hullabaloo” as a criterion would not have indicated a different decision, so nothing was lost by ignoring it.

One approach to politically sensitive value judgments is to provide R with a “parametric” analysis, where he may privately supply value judgments that he would hesitate to declare publicly.

The Senate Judiciary Committee was deciding whether to authorize a Community Anti-Crime Program, which would fund local initiatives (like Neighborhood Watch) and cost \$100 million a year. We presented committee staff with a macromodel in the form of a seven-criterion Multi-attribute Utility Analysis model. Taxpayer cost and impact on crime were the main criteria. The macro model strongly favored the bill, based on a wide range of plausible importance weights. However, we were told that the committee Chairman (Joseph Biden) was sensitive to the goodwill of the politically influential Association of Chiefs of Police, who opposed the program (since it would by-pass the regular criminal justice system). Therefore, we prudently added “electoral security” to the criteria, and passed the model to the chairman to privately enter his own importance weights. The bill failed to pass. . .

GETTING AND USING EVIDENCE

An important risk management judgment is deciding what, if any, new evidence to seek before making the main decision and how to update uncertainties in the light of what is learned. I know of no very satisfactory way to convey the underlying reasoning in information gathering decision cases. Laymen, in particular, seem to have great difficulty understanding the rationale—however expressed—of applying Bayes’ theorem.¹⁵ However, it is feasible and

¹⁵Common use of “Bayesian statistics” to refer to a broad class of methods for making inferences

useful to communicate certain elements of that reasoning and to assure that R concurs with it.

Diagnostic Updating

Prior Probability. Before evidence has been received, assessing a “prior” is the same as making any probabilistic assessment (see section titled “Assessing Risk” above). However, when R comes to update his uncertainty, he is usually already aware of the evidence, so his judgment of what his assessment *would have been* without that knowledge may be fatally contaminated. I do not even try to elicit it.

“Likelihood”. On the other hand, it can be helpful to elicit, with some care, the “likelihood” (“diagnosticity?”)¹⁶ component of Bayesian updating, from R, who will normally be the main source of the judgment.

Suppose the possibility to be predicted is an impending earthquake and the evidence is agitation among farm animals. Something like the following phrasing seems to work quite well: “How surprised would you be to see the animals agitated like this when no earthquake is imminent?” “Very.” “How surprised if an earthquake *is* imminent?” “Somewhat, but about a factor of ten less.”¹⁷

based on quantified judgment is misleading. Applying Bayes’ theorem does not have to involve human judgment and Bayes’ theorem is not the only formulation for making judgmental inferences. I prefer “personalist” inference (and decision theory).

¹⁶The standard statistical meaning of “likelihood” is probability of evidence conditional on hypothesis. However, it is often used in the literature to mean probability (e.g., “... the likelihoods of these outcomes, expressed as probabilities” on p. 20 of Ref. 23 and “... the disposal system ... shall have a likelihood of less than 1 chance in 10 of exceeding ...” on p. 11 of Ref. 9).

¹⁷The following wording, though technically accurate, would be hopelessly confusing to a layman: “What would the ratio of your probability of earthquake conditional on “agitation” be to your probability of “earthquake” conditional on “no agitation.”

Risk managers often insist on replacing of numbers by words, in this way. We did a high-level study¹⁸ recommending that the United States should somewhat lower an embargo on exporting high-powered computers to the then-Soviet bloc, on the grounds that a small increase in military threat would be more than offset by economic and other advantages. A quantitative linear multiattribute utility analysis had to be reduced to a single-page report without numbers before being submitted to the national security advisor (Henry Kissinger), who was known to refuse to read quantitative reports.

Value of Information

The rationale underlying quantitative “Pre-posterior analysis” [25], i.e., Bayesian derivation of the value of imperfect information, is still more complex to communicate to a decision analyst, let alone to a layman.

However, the following line of questioning, though still awkward, might make a recommended information strategy plausible. “How firm is your present risk assessment—that is, how much would perfect information shift it? If you were sure this research would give you that perfect information, what are the chances it would save you from a decision you would regret? How much cost would avoiding that mistake save you? How close to perfect information would this imperfect research bring you?”

A More Ambitious Rationale for an Information Strategy

The reasoning underlying a decision on what new information to seek before making a primary decision can be communicated at greatly differing levels of effort and technical sophistication, depending on circumstances.

A nontechnical congressman will rarely have more than an hour to devote to any one decision, however important (for example, the Clean Air Act evaluation discussed above). In such cases, having R answer a

¹⁸For the President’s Council on International Economic Policy [24].

few questions, as above, may be all that is feasible.

A rigorous mathematical argument would be prohibitively costly and technically challenging. However, if the problem is sufficiently important and R adequately trained, enough of the technical argument may be communicated to help R decide whether to adopt an information strategy. For example, a senior DOE official (Ben Rusche, Head of the Office of Civilian Radioactive Waste Management), a trained scientist, had to decide whether to commission a comparative study of the suitability of alternative nuclear waste sites. He in fact did have one conducted for several hundred thousand dollars [26].

In such a case, a quantitative elaboration of just part of the argument having to do with the firmness of R's risk assessment (see first question above) could be feasible and appropriate. Appendix A proposes a moderately ambitious communication process.

APPENDIX A: QUANTIFYING THE FIRMNESS OF RISK ASSESSMENTS

Several important risk communication tasks depend on the firmness or "shiftability" of R's current judgments.

1. *Plural Evaluation.* The more a risk management evaluation is liable to shift with more information or reflection, the less weight it should be given when combining it with other attempts at the same judgment.
2. *Getting More Information.* The more shiftable an evaluation, the stronger the case for more research or delay.
3. *Vulnerability to Challenge.* The more shiftable an analysis, the more vulnerable it is to legal or other challenges.

In many ways, communicating this firmness is more important than a simple assessment. It has serious action implications and is more difficult to do right, since it involves the elusive concept of second-order probability.

Two interpretations of assessment firmness need to be distinguished: assessment shift with unlimited information; and with

limited, but achievable, information. They require distinctive language and graphical devices to keep them apart. Figure A.1 illustrates them for the case where the uncertainty is about deaths in the event of a reactor accident.

MAXIMUM ASSESSMENT SHIFT WITH UNLIMITED RESEARCH

Outcome assessments, including event probabilities and estimates, may shift with new information analysis or reflection. How far could they conceivably shift with *unlimited* research and information? In particular, could they shift enough to favor a different decision?

Laymen and technical people alike commonly talk as if there were some objective "true risk" of a hazard, which risk assessment tries to approximate. Most personalists reject this view (it has been likened to the medieval theory that fire results from a substance, phlogiston, contained in an object, which escapes when it burns), but I think it has a legitimate interpretation worth communicating. It can be viewed as the point a *personal* probability would shift to if the assessor had enough information to essentially remove subjectivity. In that sense, it becomes an impersonal probability, about which we can be uncertain, and subjectively assess maximum shift distributions (contrasted with *personal ideal probability*), which is the result of perfect analysis of a given person's idiosyncratic, and therefore subjective, knowledge [27,28].

Figure A.1a shows such a distribution. The mean and range of the original risk hazard assessment is shown by a broken line on the left. Where the mean would shift to with maximum information is shown by a fan leading to a solid line. The remaining irreducible hazard uncertainty is illustrated by a new shorter broken line.

PARTIAL ASSESSMENT SHIFT WITH LIMITED RESEARCH

Unlike the familiar decision theory concept of *perfect* information, information does not

Figure A.1. Firmness of current assessment (projected shift with research).

remove all uncertainty, only as much as is feasible. It sets a tighter, and therefore more useful, bound than perfect information on the value of new information research. (But it is more elusive to define.)

Figure A.1b uses the same graphic conventions to communicate how a hazard assessment might shift with information or analysis that might *actually become available*, say, by waiting for a few years or conducting a particular research project. This is directly relevant to the decision maker in deciding whether in fact to wait for such information. If the potential shift in assessment is unlikely to change the decision, this would argue against waiting.

The limited information can be expected to shift the original hazard assessment less

than maximum information. This is reflected in the shortened vertical line in the left fan, but a longer broken line for remaining uncertainty in the right fan. (The amount of prospective information can be indicated by the thickness of the line).

COMPARISONS OF RISK ATTITUDES ACROSS INDIVIDUALS

DANIEL EGAN
GREG B. DAVIES
PETER BROOKS
Barclays Wealth, Behavioural
Finance, London, UK

GOALS IN COMPARING RISK ATTITUDES

In comparing risk attitudes across individuals, a researcher is generally looking to answer one of the three questions. The first is “can I reliably measure the difference between the risk attitudes of individual A and individual B?” This question asks if the measurements or methods that the researcher is using can reliably differentiate between individuals with different risk attitudes. The second is “what is the magnitude of the difference?” This question seeks to determine what range and variance the risk attitudes cover, and the patterns and covariates of dispersion over that range. The final question is “what factors do we need to control for to compare risk attitudes meaningfully?” This question often arises when we are comparing individuals in different circumstances and backgrounds (such as a poor laborer vs a rich financier) and groups of individuals, such as men and women, young and old, or people raised in different cultures.

Comparing these attitudes across individuals requires a clear understanding of how “people differ from one another, but remain true to themselves” [1]. Empirical evidence supporting the possibility of stable risk attitudes comes from “strong evidence that virtually all individual psychological differences, when reliably measured, are moderately to substantially heritable” [2]. Heritability of risk attitudes has specifically been found with a variety of measurement methods. Using actual investment portfolio choice as an outcome measure, roughly 30% of the

variance in choices is attributable to genetic differences, rather than environmental [3]. Tests of covariation in economic preferences roughly attribute 50% to heritable factors [4].

Further evidence of individual stability reflecting both genetic and environmental factors comes from longitudinal studies of the same individuals. Correlations in risky decision making over a three-year period range between 0.20 and 0.38 [5], and persistent individual factors accounted for 75% of the variation in responses to a risky choice regarding income levels [6]. If coarse genetics and longitudinal studies reveal stable individual differences, we may be able to design finer grained methods that reliably measure these individual risk attitudes.

In the pursuit of this goal, we first broadly review the challenges in defining comparable individual risk attitudes in the section titled “Challenges in Comparing Risk Attitudes.” The section titled “Measurements of Risk Attitude and Their Implications” introduces commonly used measurement scales and their implications for comparisons. The section titled “Elicitation Methods” details the evidence on variation of risk attitudes from commonly used elicitation methods. The section titled “Inferences in Comparing Individuals and Groups” concludes with guidance for designing studies intended to make inferences in risk attitude comparisons.

CHALLENGES IN COMPARING RISK ATTITUDES

It is essential that we first define the risk attitude we are attempting to compare. A risk attitude is not a unidimensional construct that can be easily summarized and compared using a single measure. Rather, risk attitudes are complex constructs that may be multidimensional, both across domains and within a specific domain. Moreover, there is significant evidence that empirically inferred risk attitudes are more a function of the choice context, rather than a global inherent

attitude [7–9]. To compare elicited risk attitudes, researchers should have a clearly defined risk attitude they are attempting to elicit, and understand the ramifications of elicitation method for analysis.

A key rule when making comparisons is that measurement scales and elicitation methods must be like-for-like between individuals. The *measurement scale* defines the values that an assessment can take on, and the viable inferences from it. The *elicitation method* specifies the exact mechanism by which an individual's risk attitude is revealed to the researcher. Many measures of risk attitude are notoriously sensitive to small changes in elicitation method, which has led researchers to describe preferences as “constructed” rather than “revealed” [10,11]. Constructed attitudes can be strongly influenced by the *framing* of the decision problem, such as in Kahneman and Tversky's famous Asian disease experiment [12]. Two objectively equivalent choice sets with only different wordings (number of lives potentially *saved*, rather than the number of lives potentially *lost*) caused the majority choice to flip from being risk averse to risk seeking. Thus, when comparing individual risk attitudes, we must ensure we have used the same elicitation method.

We now review factors that can bias comparisons if the elicitation method is not carefully designed.

Domain

The first challenge is defining the appropriate domain. A domain is a specific category of risk—for example, investing, health and safety, gambling, negotiations, purchasing insurance, and recreational activities. The domain dependence of elicited risk attitudes indicates that they must be carefully measured to correctly reflect risk attitudes within a specific domain. Attempting to infer investment risk attitudes from a lottery or gambling is likely to fail, as in these seemingly close domains individuals actually exhibit different risk attitudes [13–15]. Individual risk attitudes are so inconsistent across domains that they do not appear to reflect a stable person trait, implying that there is little basis for identifying a global

risk-attitude assessment instrument [16,17]. However, risk attitudes and behaviors are consistent and predictive within domain [18], indicating that focused risk-attitude assessments are meaningful and useful.

Perception of Risk

A single measure of risk attitude may mask the fact that a number of different features of the choice problem combine to form the overall *perception* of risk. Weber and Millman [19] show that people display consistent risk aversion according to their subjective perceptions of risk, but not according to theoretical measures of risk. In other words, their perceptions of risk may be derived from aspects of the choice other than the researchers' theoretical measures of risk. This divergence may then drive the degree of observed risk aversion. For example, investors show strong preferences for investing in local or well-known stocks, because the sense of familiarity leads to a perception of them being lower risk, even at the expense of diversification benefits from less well-known stocks [20,21]. Determining risky attitudes from choices may thus also require the assessment of the perceived risk of the choice [22]—an area of active research.

Framing and Risk Myopia

As detailed in the Asian disease example above, the presentation of a choice often influences the risk attitudes to a surprising degree. The implications of this in some real-world settings are alarming. Individuals show a poor ability to look at the “big picture,” resulting in suboptimal choices over time [23], over many choices, and over the whole outcome set [24]. Samuelson once noted that if you offer an individual a single 50/50 chance of gaining \$100, or losing \$50, you have few takers. However, if you offer an individual 100 such bets as a set, they are likely to take them (even though backward induction shows that this sequential choice is unsustainable) [25]. Thus, many compartmentalized *individual* decisions can result in extremely high risk aversion compared to cases where one takes a more holistic view. Similarly, individuals may react to compound

long-term prospects such as investing as if they were one-off gambles, and thus express more risk aversion than they would when using the appropriate time horizon [26].

Noise in Responses

When assessing risk attitude in any manner, we also need to consider the noise and inconsistencies that are apparent in many elicitation tasks. For example, experimental subjects frequently respond differently to the same question repeated on two occasions within the same experiment [27]. Retest reliability rates within subjects rarely exceed 70%. We can only say that one individual truly differs from another once the noise in an individual's responses is accounted for, and a number of decision-making models attempt to model such variability explicitly [28–35]. To reach the point where we can confidently assess the consistency of differences in estimates often requires many questions, and assessment of the fit of competing utility functions [36].

Incentive Effects

Inconsistency can be found between experiments using hypothetical rewards and real rewards in choice tasks. Typically, there can be a heightened sense of purpose and impact from a decision task if it is being played for real rewards rather than for hypothetical rewards. This often leads to a greater level of risk aversion being observed in tasks with real rewards [37–39], though the effect is not independent of frame [40].

MEASUREMENTS OF RISK ATTITUDE AND THEIR IMPLICATIONS

Nonutility-Based Measures for Comparing Risk Attitude

Perhaps the most general pure definition of risk aversion is that of Yaari [41], who characterizes it in terms of *acceptance sets*: individual A is said to be more risk averse than B if the set of gambles or investments that A would accept is a subset of the acceptance set of B. Individual B will accept all gambles taken by A, plus additional gambles that

are too risky for A to accept. Note that this provides us with only a rank ordering of individuals, which states that person A is more or less risk averse than person B, without any indication of the magnitude of difference between them. Using rank orderings it is possible to predict in advance that one person will make a more risk-averse choice than another person, but it is not possible to predict specific choices. It also fails to give us a complete ordering of individuals, since it can only make comparative statements about those whose acceptance sets are neat subsets of another's. Relative psychometric scales are an example of this sort of rank ordering.

A related cardinal measure is given by the *certainty equivalent* of a risky gamble. This is the amount that will make the decision maker indifferent to accepting the gamble or not, and can be elicited directly in choice tasks without subscribing to any underlying decision model. The decision maker's certainty equivalent should be equal to his valuation of the gamble.¹ If the decision maker is risk averse, then receiving the expected value of any gamble with certainty should be preferred to playing the gamble itself—thus the decision maker will accept a certainty equivalent that is lower than the expected value. Comparisons between individuals may be achieved by finding this point of indifference for different individuals playing the same gamble: the more risk-averse individual will have a lower certainty equivalent. However, note that finding a lower certainty equivalent for a single gamble only says something about the comparative risk attitudes *for that gamble* and does not necessarily translate to general statements about global risk attitudes.

Generation of a more general measure of risk attitude requires more sophisticated use of observed choices to determine an implicit utility function that would have led to these choices.² A comparison of the features of the utility function at various points can then

¹Though a multitude of possible framing effects mean that this may not be true in practice. See the section titled “Elicitation Methods.”

²Given a specific decision-making model, for example, expected utility theory.

reveal meaningful quantitative differences between individuals' risk attitudes. There are two broad methods of fitting utility functions to observed choices. Nonparametric methods make no assumptions about the appropriate underlying utility function from which observed choices are generated. They simply define the shape of the utility function from the choices themselves. Since they impose no structure on the utility function, nonparametric approaches can be the most direct translation of actual choices into the risk attitude of an individual. On the other hand, they do imply the specification of a decision model that is presumed to underlie choices. Usually the implicit assumption is that decision making is governed by the normative model of expected utility theory (EUT) [42,43] in which case risk attitudes are entirely determined by the utility function. It is nonetheless difficult to translate a nonparametric utility function over many choices to a single comparable measure of risk attitude.

Where decision making under uncertainty is assumed to be governed by a more complex mechanism than EUT, the conditions that define risk aversion can become considerably more complex than simple examination of the utility function. For example, if the most commonly utilized behavioral model of decision making, cumulative prospect theory (CPT) [44], is assumed to be the correct underlying model, then comparison of risk aversion requires separate examination of the shape of the value function for gains and losses (including loss aversion), and the shape of the decision weighting function that governs the way the decision makers distort subjective probabilities when making decisions [45]. It is possible to elicit both functions nonparametrically [46,47], but this is complex and means that it is impossible to arrive at a simple comparison of risk aversion.

Parametric methods presume both a specific decision model and a specific form for the functions within this model (e.g., a power utility function). The function that is arrived at then is much "smoother" than nonparametric utility—in effect, parametric methods seek to abstract from the noise inherent in observed behavior to provide a "cleaned" estimate of the underlying utility function that

could have produced them. This enables a set of risky choices to be described in just one parameter (or more for complex models), which can then be more readily compared between individuals. However, the choice of model and utility function determines (possible incorrectly) the resulting measures of risk attitude.

Utility-Based Measures for Comparing Risk Attitude

If we are prepared to assume that the individual's decisions are governed by the underlying model of EUT, then Yaari's definition is identical to the requirement that the more risk averse person has a more concave utility function.³ In addition, under EUT one person having a more concave utility function than another ensures that this person also has a lower certainty equivalent than another for all gambles.

Utilities themselves are not unique—any affine transformation of a utility function describes the preference set equally well—so we cannot directly compare risk attitudes by comparing utilities. However, the most prevalent utility-based formulations of risk attitude are the Pratt–Arrow coefficients of constant absolute risk aversion (CARA) and constant relative risk aversion (CRRA) [48,49], which are measures of curvature at a point on the function, standardized by dividing by the first derivative to ensure that the ratios are in comparable units, and so are comparable across individuals [50].

The absolute coefficient (CARA) is a direct measure of the degree of concavity of the utility function at the point of *initial* wealth:

$$-\frac{u''(w_0)}{u'(w_0)}.$$

The relative coefficient (CRRA) measures the degree of aversion to risks over percentage changes of wealth from the point of initial wealth:

³A utility function that has zero curvature expresses risk neutrality, and a convex utility function expresses risk seeking.

$$-w_0 \frac{u''(w_0)}{u'(w_0)}.$$

These coefficients measure the *local* curvature at this point, and thus only refer to risk attitudes to “small” gambles (those with infinitesimal variance). Although an advantage of a parametric utility function approach is that measured risk attitudes can be generalized to gambles that are not included in the initial measurement set, we need to remain aware that this generalization may not be accurate beyond the range of outcome values spanned by this set of sample gambles. Nonetheless, the local Pratt–Arrow coefficients are the most frequently used measures of risk aversion when comparing risk attitudes.

ELICITATION METHODS

Our measures of risk attitude depend on the elicitation method used to determine them; thus different methods may give different results for the same person. Different methods of eliciting risk attitudes have been shown to result in different risk-seeking or risk-averse classification, as well as different rank orderings across methods [51–53]. Thus when using different elicitation methods, we are implicitly comparing both individuals and methods. When we have comparable risk-aversion estimates (e.g., CRRA estimates) *across* elicitation methods, we can check if these estimates are consistent with each other. Some measurement methods give systematically different results than others.

To clarify the ways in which methods may influence measurements, Fig. 1 depicts the possible measurements from the same individuals (the circles) using different elicitation methods (lines A through F).

Specific problems with comparisons of individual risk attitudes, which can be observed from the graph in Fig. 1, include the following:

- *Distance versus Rank.* While A and B maintain rank ordering of individuals, they differ in the distance between them.

Figure 1. Potential moves in risk-attitude assessment.

- *Rank versus Category.* While A and C maintain rank ordering of individuals, method C reveals risk seeking for all individuals, while A reveals risk aversion.
- *Straddling Risk Neutrality.* Method D reveals risk aversion for one individual, risk neutrality for another, and risk seeking for the last. This means that certainty equivalents vary between positive and negative.
- *Rank versus Rank.* A and E find risk aversion for all individuals, but do not maintain the same rank ordering as A.
- *No Consistency.* Compared to method A, method F results in completely unrelated risk-attitude differences. The rank, dispersion, and risk aversion/seeking have all changed from those in A.

We now review specific methods of eliciting individual risk attitudes, and discuss the strengths and weaknesses of comparing outcomes from each.

Relative Psychometric Methods

Psychometric measurement is the simplest risk-attitude measurement method in terms of elicitation, analysis, and inference. While the use of psychometric techniques is long established in the fields of personality and cognitive psychology, it is relatively new to risk-attitude measurement. Psychometric risk-attitude assessment usually involves posing large sets of simple, usually bipolar,

statements such as “investing in stocks is something I do not do, since it is too risky” [54]. Individuals then indicate agreement along a simple scale of “strongly disagree” to “strongly agree” or similar. Using statistical techniques such as factor analysis, questions that are systematically related are revealed, and represent a potential measurement of the latent trait. More complex models based on item-response theory explicitly model the discrimination of each question, and use weighted scores to generate higher differentiation with fewer items [55].

The psychometric method has a number of advantages: questions are intuitive and quick for individuals to respond to, and do not require numeric or statistical calculations, which avoids confounds such as numeracy [56]. They give a stable measure of risk attitude invariant to changes in outcome expectations [57]. They accord well with self-assessments of relative risk aversion, and correlate in the expected direction with demographic factors such as gender and age [58]. Moreover, most psychometric scales are inherently differentiating across individuals, as the process of determining which questions best represent latent traits leads one to include questions that encourage variation. As a result, psychometric risk-attitude scales give an efficient, reliable, and stable rank ordering of individual risk-attitudes. They score highly on test–retest validity and internal consistency (e.g., Cronbach’s α [59]).

The limitation of psychometric risk-attitude measurement is that individuals are dispersed on a sample-based ordinal scale [60], and thus there is no direct link to quantitative measures of risk aversion. As individuals’ responses do not explicitly map to a utility function, comparisons of individual risk attitudes are restricted to comparisons of rank order. This renders comparisons based on magnitude of difference meaningless, and does not allow the researcher to explicitly categorize the respondent as risk averse or risk seeking.

Initial linkages from psychometric scales to quantitative measure of risk attitude have been encouraging. In a broad and detailed study, psychometric risk attitudes were

found to correlate well with not only standard CRRA survey questions but also CARA estimates of holdings in household portfolios [54]. A carefully controlled longitudinal study revealed that while self-directed investors risk and return expectations changed, their psychometric risk tolerance was remarkably stable [57], and was the best predictor of investment into the stock market over a volatile period when expectations were changing rapidly. In a focused set of graphical risky-choice experiments, individuals with higher psychometric risk tolerance chose riskier investments, even when the outcome distributions were significantly non-normal. Using a CRRA risk attitude to manipulate an experimental design, the researchers provided strong evidence that the psychometric scale was linkable to quantitative measures of risk aversion [61]. Faff *et al.* [13] find that the psychometric risk tolerance measurements are “strongly aligned” to the risk-aversion coefficient implied by lottery choices, and this parallel increases as the stakes of the lottery size increase. Thus, the ease, reliability, and validity of psychometric scales may outweigh the lack of direct mapping to numerical measures of risk aversion.

Experimental Methods and Choice Tasks

Many studies have examined individual risk attitudes using quantitative and experimental techniques, stimuli, and response modes. Importantly, the choice task setup does not necessarily assume any *ex ante* risk attitude, decision theory, or utility functional form. The researcher observes choices and then attempts to explain the choice by fitting a model. Some of the most common elicitation methods are pairwise choice tasks [36,62]; valuation tasks using the Becker *et al.* [28] method or asking for a certainty equivalent or probability equivalent to a risky situation [63]; and ranking tasks [64] or the trade-off method to find points on the utility curve that are equidistant from each other [47]. In many of these studies, statistical analysis is used to estimate parameters of a utility function, such as the CRRA coefficient [41,49,65,66] or the value function in CPT [44], or a nonparametric approach is employed to determine the shape of the utility function.

The benefits of well-designed choice tasks are that they isolate individual risk attitudes and remove potential confounds. The ability to control the interactions between the multivariate factors that can influence risk attitudes enables the researcher to have a much deeper understanding of each in isolation. However, this means that the nature of the interactions can often remain a mystery and reduce the applicability of experimental results to real-world situations.

One of the main disadvantages for experimental choice tasks is that the precision of the elicitation method can often lead to internal inconsistency in the pattern of observed attitudes within individuals. Perhaps the most robust of these is the preference reversal phenomenon [40,67,68], where individuals state their certainty equivalent for two risk situations with the same expected value—one involving a small probability of a large gain (often called the *\$-bet*), and the other involving a large probability of a small win (*P-bet*). Individuals tend to place a higher certainty equivalent (and hence signal a preference) on the *\$-bet*. However, when faced with a direct choice between the *\$-bet* and the *P-bet*, individuals tend to choose the *P-bet* even though this is inconsistent with their previous valuations.

There are also large changes in risk attitude *within individuals* between estimates derived from a first price auction and the BDM (Becker-DeGroot-Marschak) procedure [53]. Isaac and James [53] found that the majority of individuals exhibit more risk seeking in BDM, and the rank ordering of individuals was not preserved. Those that appeared to be the most risk averse in the population under the first price auction tend to be ranked as the most risk seeking in BDM. As a result, comparisons between individuals are difficult to make as they cannot be shown to be consistent even *within* subjects.

Observed Behaviors

Finally, many studies attempt to infer attitude to risk by observing individuals' actions, often in the natural environment in which they make them. This approach

has a number of advantages, most regarding validity. Compared to questionnaire-based assessments, which are usually performed on a demographically restricted sample (i.e., college students), observed behaviors can be assessed in a wide variety of circumstances for more representative samples. Observed behavior studies also benefit from "natural validity," that is, they measure the risk attitude being evidenced in its natural environment. A standard measure of questionnaire and experimental instrument validity is whether it correlates meaningfully with observed behaviors—an easy standard for measures based on observed behaviors to pass.

The downside to observed behaviors is that the reduced control over sample, control variables, and environmental stimuli means that inferences regarding risk attitude may be significantly confounded. As a result, the number of assumptions in observed behavior studies is much larger, the fragility of data analysis is higher, and the ability to make causal inferences is limited. For example, Nosić and Weber [57] found that changes in expectations for stock returns drove changes in the risky allocation proportion, rather than changes in risk aversion. Thus, observed behavior studies may confuse variables that lead to the same outcome—increasing or decreasing apparent risk of the decision—unless confounding variables are controlled for.

A plethora of studies use investment holdings to estimate risk-aversion coefficients [69–75] and compare them across populations. Such studies have also been concerned with the question of whether absolute and relative risk aversion are decreasing, constant, or increasing with wealth levels, with the majority concluding that absolute risk aversion is decreasing [73] and that relative risk aversion is approximately constant or slightly increasing. In addition, many have also used surveys to supplement their understanding of the individuals, resulting in better controlled studies. However, all these studies suffer from the fact that on-line trading accounts most likely represent only a fraction of the individuals' total wealth, and risk-aversion estimates are biased toward a

financially savvy and risk-seeking sample of the public. Much recent activity has used the natural experiment of game shows such as “Jeopardy” and “Deal or No Deal” to estimate risk coefficients [76,77], with the results giving mixed implications for functional forms of CRRA and CARA estimates [78]. The estimated utility function strongly evidenced increasing relative risk aversion (IRRA) [78]. Cohen and Einav structurally estimate risk aversion using car insurance data, and find systematically higher coefficients than much of the existing data [79].

INFERENCES IN COMPARING INDIVIDUALS AND GROUPS

We often want to make general statements such as “person A is more risk averse than person B” or “in general risk aversion increases with age” or even “we must increase a woman’s income by X to make her exhibit risk aversion equivalent to that of an average man.” When comparing risk attitudes in this way, we must ensure the comparison accounts for other factors that may influence the estimated risk attitude. Interestingly, the advice is quite similar for making comparisons in the case of both individuals and groups. Individuals whose circumstances are different may perceive the same objective risk differently, and thus observed behaviors and choices may differ because of the perception of risk, rather than risk attitude [19,80]. An individual’s wealth level, background risk, income risk, and the culture the individual has been raised in all contribute to apparent risky behavior in ways that may bias risk-attitude comparisons. This is not to say that valid comparisons cannot be made, but rather that they must be made carefully, with required individual-level controls.

Control Variables across Individuals and Groups

When making comparisons of risk attitudes, we often ask questions about groups of individuals who differ in some respect. Common questions often involve differences by gender [81], age [75], education level [82], and culture [83]. These variables have been

found to have a systematic effect upon risk-taking behavior across many studies. While the causal mechanism for these differences may vary in direction, it nonetheless means we must account for them when making comparative assessments of individual risk attitude. Whether one should control for these systematic variations depends on the purpose of the comparison.

To make this dependency clear, imagine that you have representative samples from two different groups—group X and group Y. Group X has a significantly higher average risk aversion than group Y according to your measurements. However, group X also has a significantly higher proportion of females than group Y (in the overall population). As there is significant evidence that females are generally more risk averse, the difference in overall measures of risk aversion may be due to differences in gender composition. If the question we are asking is “what is the distribution of risk aversion for an individual belonging to group X?”, then the nonadjusted figure is appropriate—it accurately reflects the probability of observing a given risk attitude conditioned on observing that the individual belongs to group X.

However, if we are seeking to say “belonging to group X is associated with, or causes higher risk aversion,” we are making a different statement that requires adjustment for related factors. We cannot say belonging to group X causes or results in “higher” risk aversion compared to belonging to group Y without controlling for sex. Any grouping variable that is correlated with other factors influencing risk attitudes must be controlled for, before the independent association of risk attitude and grouping can be assessed. Only by controlling for other factors that influence risk attitudes can we say “belonging to group X is associated with higher risk aversion.”

Wealth Level

One of the most common assumptions made in economic models is that individuals’ preferences exhibit CRRA: their attitudes to gambles over identical percentages of wealth remain constant regardless of their wealth levels. This is intuitively plausible—we would expect a millionaire to be more cavalier

about a £ 10 gamble than a pauper; but there is no clear intuition about why a millionaire should be more or less averse to gambling 10% of his total wealth than his companion. Indeed, long-run macrobehavior of the economy would argue that this assumption must be approximately correct. As Campbell and Viceira [50] argue, “per capita consumption and wealth have increased greatly over the past two centuries ... Interest rates and risk premia do not show any evidence of long-term trends in response to this long-term growth; this implies that investors are willing to pay almost the same relative costs to avoid given relative risks as they did when they were much poorer, which is possible only if relative risk aversion is almost independent of wealth.” On the other hand, a number of studies of household portfolios have shown that the share of total household wealth invested in risk assets is increasing with wealth [84–86], which would imply decreasing relative risk aversion (DRRA).⁴

Rabin [66] noted that the risk attitudes that are arrived at by functions fitted to gambles over small amounts result in implausibly high degrees of risk aversion (which are not observed) for choices over large amounts. This casts some doubt on the levels of risk aversion measured through experimental methods using small gambles (though relative comparisons of risk aversion between individuals may still be stable and correct even if the levels are not). Holt and Laury [37] investigated the relationship between real and hypothetical gambles, crossed with small versus large stakes [37]. They found a larger increase in risk aversion along higher stakes in real gambles compared to hypothetical gambles. Similarly, Brinswanger [38] and Kachelmeier and Shehata [39] examined risk aversion over real high stakes corresponding to between one and three months of actual income in rural India and China. They likewise found IRRA as the stake size increased.

⁴One resolution of this apparent conundrum is that less wealthy people face greater relative external (nonfinancial) risks and thus need to compensate for these by reducing the proportion of investible wealth allocated to risky assets.

If individuals do not exhibit CRRA or CARA, then it is much more difficult to compare numerically elicited risk attitudes. Risk aversion evidenced over the same value (\$,£) may vary by background wealth, or the percentage change in wealth, making comparisons between the poor and the rich meaningless.

Culture

Another confounding factor is the individual's culture or background [87]. While risk attitudes, that is, trade-offs of expected risk and return, do not vary tremendously across cultures [80,88], risk perceptions do [89]. Subsumed within the general model is the fact that *perceived* risk is what is relevant when understanding risk attitudes [90,91]. Cultural differences posited to explain these differences in risk perception include the individualism/collectivism dimension [80,92], trust in institutions such as the stock market [83,93], and propensity for regret [83]. These differences mean that while comparisons of risk attitude *within* culture are relatively straightforward, risk attitudes across cultures are less clear. Once individual differences in circumstances are controlled for, the relationship between investment choices and risk attitudes may be the same for all cultures. Thus, controls for relevant individual-level circumstances are necessary for making statements about comparative risk attitude viable.

GUIDELINES FOR DESIGNING STUDIES

As much of the preceding review has shown, comparisons of risk attitudes have many pitfalls deriving from the elicitation method, domain, culture, and measurement precision used. However, this should not deter would-be researchers from investigating differential risk attitudes. In this section, we discuss the guidelines that a researcher can use when designing a study or analyzing data comparing risk attitudes and their determinants.

The ideal risk-attitude measurement study would involve triangulation using repeated measurements across different elicitation methods. First, the individual should

answer enough questions such that the size of the noise (error term) *within elicitation method* can be estimated. This allows us to specify the degree to which differences in estimates are based on consistent differences, rather than noise. Second, individuals should answer questions *across measurement methods*. This allows us to determine the extent to which a given elicitation method may systematically result in higher or lower apparent risk aversion or seeking. The researchers can then decompose the observed estimates into method-specific and individual-specific variance, which allows them to use the *intraclass correlation coefficient*. This coefficient is a measure of the number of choices that are explained by fixed individuality, while allowing task structure and noise to be independently measured [94,95].

Survey and Experimental Designs

When designing a study investigating risk attitudes across individuals, the researchers should first carefully think about exactly what risk attitude they are attempting to measure. There is large extant literature in many domains on how risk is defined, and the researchers should have a clear understanding of the attractions, downsides, and variance of potential outcomes specific to that domain.

Secondly, the researchers should consider what type of analysis they need to perform to answer their research question appropriately. This will often drive the type of measurement scale that must be used to define the risk attitude, such as ordinal or interval. Some risk attitudes are more amenable to quantification (e.g., investing as opposed to social risk), and thus in many domains the measurement scale may be constrained to being ordinal. Given the higher demands that are placed on individuals responding to quantitative and probabilistic questions (used to construct interval and cardinal scales), and the fragility of such measurements, researchers should use them only if magnitudes of differences between individuals are core to the hypothesis.

Finally, the researchers need to choose an elicitation method. The method often codepends on the measurement scale that

can be determined from it, but there are often many ways of obtaining measurements using different methods. All elicitation methods have their own strengths and weaknesses in terms of ease and brevity, stability and validity of responses, and ability to discriminate between noise in responses and significant differences. An ideal elicitation method would combine the positive aspects mentioned above.

Observational Studies

As noted above, the main limitation in observational studies is the potential sample selection, a lack of controls for confounding variables, endogeneity of individual circumstances, and a lack of control over stimuli. When analyzing observational data, there are two key considerations that a researcher must answer. First, on what basis are we attributing the observed choices to differential risk attitudes as opposed to other noncontrolled variables such as education, familiarity, or nonrisk preferences? Second, are measurements valid as a measure of the relevant population, or might they reflect self-selection in riskier or less risky activities?

Recently much progress has been made in mitigating these shortcomings using “natural experiments” [96]. Natural experiments allow the researcher to specifically manipulate the natural circumstances in which a subject is operating, which can reduce sample bias, improve control of stimuli, and even provide strong control variables [97].

COMPETING RISKS AND LIMITED FAILURE

SANJIB BASU
Division of Statistics,
Northern Illinois
University,
DeKalb, Illinois

INTRODUCTION

In engineering, biomedical, or other studies involving time-to-event outcomes, the units or subjects involved can sometimes experience the time-to-event in different ways. In engineering studies, the event of interest is typically failure of the unit, whereas in biomedical studies the event can be survival or recurrence of disease. The event often results in termination (or restart) of follow-up or inspection process, so that occurrence of the event in one way hinders the occurrence of other types of events. In such cases, the statistical analysis can be performed using the theory of competing risks. Each unit or subject is exposed to many competing risks, one of which causes the failure, unless the unit/subject is right-censored, that is, it does not fail within the follow-up duration. Examples of failure data obtained under competing risks are abundant in reliability and biomedical applications. In engineering applications, the individual causes or risks may signify the risks of failure of individual components or subsystems that comprise an entire system. Occurrence of a system failure is caused by the earliest onset of any of these component failures. In this respect, the framework is that of a system with components connected in a series. Alternatively, the competing risks may signify the multiple modes of failure for a complex unit. In biomedical setting, the competing causes of failure (a failure may indicate death or relapse or other time-to-event outcome) typically refer to various potential

risk factors for a subject (or an animal or a cell) observed in a study. For example, for a breast cancer patient, the competing risks may include breast cancer, other cancers, heart disease, as well as risk from other diseases. The effects of the other competing risks may play an important role in survival studies on slowly progressing diseases.

In some lifetime applications, a fraction of the subjects or units continue to survive one or some of the risks. A classic example of this in industrial applications is the case of infant mortality where some of the units may fail from the risk of infant mortality while others may survive it. The surviving units however, may fail from other risks, such as the risk of wear out. It is seen from an analysis of cancer survival data that an increasing proportion of patients are being cured of cancer because of advances made in treating the same. These patients, however, continue to be exposed to other risks/diseases.

In applications of lifetime data associated with competing causes of failure, an additional complication may arise when the true cause of failure is not exactly identified for a certain subset of the units or subjects. The causes of failure of such items are generally referred to as *masked*. Masking can be complete or only partial when the cause of failure of the unit is narrowed down to a subset but is not exactly identified. In engineering applications, masking often results from an attempt to expedite the process of repair by replacing the entire subset of components responsible for failure instead of further investigation toward identifying the specific cause for failure. In biomedicine, masking indicates lack of or partial knowledge for the cause of the event (death, relapse, etc.), which could be due to lack of complete investigation or partial loss of patient record. In practice, one possibility is to carry out a second stage analysis to uniquely determine the cause; however, statistical inference is possible even when the cause of failure is masked for a subset of systems.

COMPETING RISKS AND LIMITED FAILURE MODELS

The Limited Failure Model

In industrial applications, the occurrence of early or “infant mortality” failures is an important problem. A production lot may contain a few defective units even after a quality control screening. These units with manufacturing or other defects will usually lead to an infant-mortality failure early in their lifetime after they have been operated for some period of time. The nondefective units, on the other hand, are expected to operate unless they are abused in their application and are not expected to fail from the risk of infant mortality. Meeker [1] and Chan and Meeker [2] termed this a *limited failure population*. We note that though the limited failure population is considered in the context of risk from infant mortality, it may apply to other risks of failure as well.

In the context of survival data, limited failure models, which are known as models with surviving or cure fractions, have been considered mostly in the analysis of cancer survival or recurrence. As cancer therapy progresses, the curability of many cancers is becoming a reality. The treatment of cancer has shown substantial progress with an increasing proportion of patients being cured from many types of cancers. The chances of being cured and the survival time since diagnosis are of interest to cancer patients and the medical community alike. From a statistical perspective, when the survival or time-to-recurrence curve for cancer tend to plateau at a value strictly greater than 0, it is taken as an indication of the presence of a proportion of cured patients for whom cancer will not recur.

The probability of being failure-free, also known as the *cure rate* or the *surviving fraction*, is defined as the asymptotic value of the survival function $S(t)$ as $t \rightarrow \infty$, that is,

$$p = \lim_{t \rightarrow \infty} S(t). \quad (1)$$

Here, $S(t) = P(T > t)$ is the survival function for the underlying random variable T . Whenever $p > 0$, the random variable T has a probability mass at infinity (or at an arbitrarily large time point).

Different models have been proposed to analyze time-to-event data with a failure-free fraction. The mixture cure model of Boag [3] (see also Berkson and Gage [4] and Farewell [5], and Maller and Zhou [6]) assumes that a fraction of the units or individuals are failure-free from time 0 and will never experience the risk of interest (infant mortality or cancer). The remaining fraction are exposed to the primary risk (as they have manufacturing or other defects in the case of infant mortality or not-cured in the setting of cancer survival). An alternative cure rate model, known as the *bounded cumulative hazard model*, was proposed in Yakovlev *et al.* [7] and has a growing literature [8,9]. This model defines an asymptote for the cumulative hazard and hence for the survival function.

Boag [3] first proposed the two-component mixture cure model. Berkson and Gage [4] proposed a model that included a background mortality rate and a constant excess mortality for the uncured group. Anscombe [10], Danziger [11], Goldman [12], Greenhouse and Wolfe [13], and Lloyd and Joe [14] considered the mixture cure model under exponential distribution assumption, whereas Bandes and Nadas [15] used the lognormal distribution and Steinhurst [16] used the Weibull distribution. De Angelis *et al.* [17] and Phillips *et al.* [18] simultaneously modeled the cure fraction and the hazard in the uncured group. Verdecchia *et al.* [19] used similar models to estimate and project cancer prevalence. Gamel *et al.* [20], Yu *et al.* [21], and Yu and Tiwari [22] modeled the relative survival from cancer. For an extensive list of reference on mixture cure model, see Tsodikov *et al.* [9].

Meeker [1] provides an example of a limited failure population in an engineering setting that involves life test of 4156 integrated circuits from a pilot production process. In the life test, 28 failures were recorded up to 593 h. The test was continued until 1370 h without another failure. Both engineering judgment and analysis of the data by Meeker indicated that a few more failures would have been observed if the

test on the other 4128 units had been continued.

Competing Risks

Competing-risks failure data and their analysis have an extensive literature and range from studies on survival analysis in biostatistics to applications of reliability in engineering to risk models in actuarial science. Crowder [23] is an excellent resource for statistical theory and analysis of competing risks. The more recent book by Pintilie [24] emphasizes practical application of competing risks theory, mostly in biomedical applications. The 2006 special issue of JSPI [25] contains a wealth of references. In recent engineering applications, Langseth and Lindqvist [26] considered an interesting application of competing risks models in the repairable systems, whereas Bunea and Mazzuchi [27] studied competing failure models in accelerated life testing. Sun and Tiwari [28] analyzed the failure times of small electric appliances that may fail due to two competing risks. Parametric analyses of the competing-risks model were proposed by David and Moeschberger [29], Lagakos [30], and Prentice *et al.* [31]. Cause-specific hazard functions were used in nonparametric estimation by Nelson [32], Aalen [33], and Crowder [23]. Semiparametric methods based on proportional-hazards models were discussed by Kalbfleisch and Prentice [34] and Lawless [35].

The latent failure times approach to competing risks [29], which is also the prevalent approach in most engineering applications, is based on latent failure times $Y_r, r = 1, \dots, R$, corresponding to time-to-failure from competing risks $r = 1, \dots, R$ with associated marginal survival function $S_r(\cdot)$ and marginal hazard $h_r(\cdot)$. Thus, while the units or subjects are exposed to $R \geq 2$ competing risks acting simultaneously, this approach is based on the potential failure time Y_r from risk r that would be observed if the possibility of failure from causes other than r were removed from the unit or subject. The observed lifetime T is then taken to be $T = \min(Y_1, \dots, Y_R)$. If $S(t) = P(T > t)$ is the survival function

for the observed lifetime T , then under the assumption that the potential failure times $Y_1, \dots, Y_R$ from the R competing risks are independent we have $S(t) = \prod_{j=1}^R S_j(t)$. The potential failure time model has been criticized [31,34] since in many cases, especially in biomedical applications, either it is not feasible, or it is physically impossible to remove all other risks from the system. The alternative cause-specific hazard formulation [31,34,36]) is based on the joint distribution of the observed survival time T and cause-of-failure C . In particular, let $S(r, t) = P(C = r, T > t)$ be a “subsurvival” function with $S(t) = \sum_{r=1}^R S(r, t)$ denoting the marginal survival function of T . The corresponding subdensity function is denoted as $f(r, t)$. The cause-specific or subhazard function

$$\begin{aligned} h(r, t) &= \lim_{\delta \rightarrow 0} \frac{P(C = r, T \leq t + \delta | T > t)}{\delta} \\ &= \frac{f(r, t)}{S(t)} \end{aligned} \quad (2)$$

is the instantaneous failure rate from cause r at time t after surviving all risks $1, \dots, R$ up to time t . The cause-specific subhazard functions $h(r, t)$ are thus defined in terms of the joint distribution of the observed time and cause of failure (T, C) . The overall hazard from all risks combined is $h(t) = \sum_{r=1}^R h(r, t)$.

Independence of the potential failure times $Y_1, \dots, Y_R$ implies that failure time from risk r under one set of study conditions in which all R risks are operative is precisely the same as under an altered set of conditions in which all risks except the r th risk have been removed. However, the elimination of certain risks may well alter the hazards from other causes making the independence assumption of questionable validity [30]. If independence is assumed, then the latent and cause-specific approaches lead to identical statistical inference [23,34]. Moreover, for any competing risks model with a joint survivor function $\bar{F}(y_1, \dots, y_R)$ that may imply dependence between $Y_1, \dots, Y_R$, there exists a different joint survivor function in which $Y_1, \dots, Y_R$ are independent such that both models reproduce the same set of sub-survival functions $S(r, t)$. In particular, one

cannot distinguish between the dependent model and the proxy independent model based on observations on (C, T) alone. This is the well-known identifiability problem [23,37,38]. In fact, each such dependent model has a whole class of proxy models (not necessarily independent). Heckman and Honore [39] showed that when there are explanatory variables in the model, identification of the joint survivor function $\bar{F}(y_1, \dots, y_R)$ is possible from the subsurvivor functions within a certain framework. Slud [40] proved a result of similar spirit under a different setup. Identifiability can also be regained with specific parametric forms. Basu and Ghosh [41,42] and Basu and Klein [43] established identifiability of competing risks models for many parametric distributions. Moeschberger and Klein [44] provided a review of analytic approaches for handling competing risks data when the independence assumption is suspect. We note here that parametric forms are common in reliability applications, whereas non- or semiparametric ones are more popular in biomedical applications.

Another approach to competing risks is the relative survival approach, which is sometimes used in biomedical, especially epidemiological, applications. In this approach, the “expected survival” from causes other than the primary risk is estimated from the general population and the relative survival from the primary risk is obtained as the ratio of the overall survival to the expected survival from other causes. Gamel *et al.* [20], Yu *et al.* [21], Yu and Tiwari [22], and Lambert *et al.* [45] considered the relative survival approach. The relative survival is the same as the net survival from cancer if expected survival (from other risks) in the general population is assumed to be the same as the net survival from other causes for the units under study and if the risks of primary risks and other causes are assumed to act independently. This independence assumption is implicit in many works that use the relative survival approach; without this assumption, relative survival can be interpreted only as a ratio [46]. The *independence assumption*, however, is not testable within a fully competing risks framework

(without further structural or parametric assumptions) due to identifiability issues as noted before [23,34,38].

If *independence* holds, it follows that the marginal hazards $h_r(t)$ equals the subhazards $h(r, t)$. The equality of marginal and subhazards is, in fact, weaker than the independence assumption [23] and is often known as the *Makeham assumption* [47].

Competing Risks and Limited Failure

Let $\{(T_i, C_i), i = 1, \dots, n\}$ denote the data from n units or individuals where T_i is the time-to-event and C_i denotes the cause-of-event for the i th unit. Here $C = 1, \dots, R$ denotes the R competing risks and $C = 0$ denotes the primary risk under study. We use $C = 0$ to denote the case when the event is right-censored and assume that the censoring process is noninformative.

The mixture cure competing risks model postulates that fraction p of the units or individuals will be failure free from the primary risk, whereas the remaining $(1 - p)$ fraction will eventually fail from the primary risk if complete follow-up were possible. The population is thus assumed to be a mixture of “risk-free” (from primary risk) and “risk-prone” groups, but the separation between these two groups is latent. In particular, for each unit i , let Q_i be a latent binary indicator, with $Q_i = 0$ and $Q_i = 1$ denoting the risk-prone and risk-free cases, respectively. The joint likelihood of time and cause can then be written as

$$p(C_i = r_i, t_i) = (1 - p)P(C_i = r_i, t_i | Q_i = 0) + pP(C_i = r_i, t_i | Q_i = 1). \quad (3)$$

Basu and Tiwari [48] modeled these two terms corresponding to the latent risk-free and risk-prone groups separately. In particular, in their cause-specific hazard formulation, let $h(C = r, t | Q = q) = h(r, t | q)$ denote the cause-specific hazard from risk r in latent group $Q = q$. When $Q = 1$, that is, in the risk-free group, the units are failure-free from the primary risk of $r = 1$. In particular, there is no hazard from Risk 1 in this group, or $h(C = 1, t | Q = 1) = h(1, t | 1) \equiv 0$ for all $t \geq 0$. The overall hazard in the

Table 1. Hazard Functions of Common Lifetime Distributions

Distribution	$h(t)$	μ, τ	Transformation	$h^0(z)$
Exponential	λ	$\mu = -\log \lambda, \tau = 1$	$z = \log t - \mu$	$\exp(z)$
Weibull	$\lambda \gamma (\lambda t)^{\gamma-1}$	$\mu = -\log \lambda, \tau = \gamma$	$z = \tau(\log t - \mu)$	$\exp(z)$
Lognormal	$\frac{\tau \phi(z)}{1 - \Phi(z)}$	$\mu = \lambda, \tau = \gamma^{-1}$	$z = \tau(\log t - \mu)$	$\frac{\tau \phi(z)}{1 - \Phi(z)}$
Log-Logistic	$\frac{\tau \exp(z)}{1 + \exp(z)}$	$\mu = \lambda, \tau = \gamma^{-1}$	$z = \tau(\log t - \mu)$	$\frac{\tau \exp(z)}{1 + \exp(z)}$
Gumbel	$\frac{\exp(e^{-z}) - 1}{\tau \exp(-z)}$	$\mu = \lambda, \tau = \gamma^{-1}$	$z = \tau(\log t - \mu)$	$\frac{\exp(e^{-z}) - 1}{\tau \exp(-z)}$
Gompertz	$\gamma \exp(\lambda t)$			
Gamma	$\frac{t^{\gamma-1} \exp(-\lambda t)}{\int_t^\infty x^{\gamma-1} \exp(-\lambda x) dx}$			

risk-free and risk-prone groups is given by $h(t|Q=0) = \sum_{r=1}^R h(r, t|Q=0)$ and $h(t|Q=1) = \sum_{r=2}^R h(r, t|Q=1)$, respectively.

The individual $(2R-1)$ cause-specific hazards $\{h(r, t|Q=1), r=2, \dots, R\}$ and $\{h(r, t|Q=0), r=1, \dots, R\}$ for the two latent groups can be modeled using standard hazard models, either semiparametrically as a piecewise constant function or parametrically. Parametric models are more common in engineering applications. A general class of parametric models is given by the location-scale structure

$$h(r, y|q) = \tau_{qr} h_{qr}(\tau_{qr}(y - \mu_{qr})) = \tau_{qr} h_{qr}^0(z), \quad (4)$$

where $z = \tau_{qr}(y - \mu_{qr})$ with some abuse of notations and the base hazards $h_{qr}^0(\cdot)$ are free of parameters. This location-scale family includes a large family of distributions that are traditionally used to model lifetime data (when the failure time is suitably transformed, say, to a log-survival time) and includes the exponential, Weibull, log-normal, log-logistic and Gumbel distributions (Table 1). The Gamma, Gompertz and three-parameter generalized Gamma distributions [21] do not have the location-scale structure; however, they also have tractable parametric forms.

Let θ_{qr} denote the parameters in the sub-hazard $h(r, t|q)$ (for example, $\theta_{qr} = (\mu_{qr}, \tau_{qr})$) and let $\theta_0 = (\theta_{0r}, r=1, \dots, R)$, $\theta_1 = (\theta_{1r}, r=2, \dots, R)$ denote the collection of parameters from the subhazards of all the competing

risks in the two latent groups. Basu and Tiwari [48] considered a Bayesian approach and assumed a joint prior distribution $p(\theta_0, \theta_1, p)$ on the collection of parameters. For example, one can assume prior independence across the latent groups and the risks and assign independent priors for the θ_{qr} parameters, $q=0, 1, r=1, \dots, R$.

On the basis of these general formulation with R competing risks and limited failure from the primary risk ($r=1$), the likelihood of cause and time of event data from n units or individuals $\{t_i, c_i, i=1, \dots, n\}$ can be written as

$$\begin{aligned} & \prod_{i=1}^n \left[(1-p) h(c_i, t_i|Q=0, \theta_{0,c_i})^{I(c_i \neq 0)} \right. \\ & \quad \times \exp \left\{ - \sum_{r=1}^R H(r, t_i|Q=0, \theta_{0r}) \right\} \\ & \quad I(c_i \neq 1) p h(c_i, t_i|Q=1, \theta_{1,c_i})^{I(c_i \neq 0)} \\ & \quad \left. \times \exp \left\{ - \sum_{r=2}^R H(r, t_i|Q=1, \theta_{1r}) \right\} \right]. \quad (5) \end{aligned}$$

We recall here that $c_i = 0$ is used to denote the right-censored cases. Further, if a unit failed due to the primary risk ($c_i = 1$), then it cannot be risk-free from the primary risk and thus the second term in Equation (5) does not apply in this case. Finally, the case of masked causes (when the cause-of-event c_i is not exactly recorded) is not covered

in Equation (5); this case is deferred to the section titled “Masked Causes”.

MASKED CAUSES

The causes of event for some of the units or individuals sometimes are not exactly identified or recorded. This is known as *masking* in competing risks literature. Partial masking refers to the case when the cause is narrowed down to a subset of the risks $\{1, \dots, R\}$ but not exactly identified, whereas complete masking means that the cause can be any one of $\{1, \dots, R\}$. Early works on competing risks with masked causes include Racine-Poon and Hoel [49], who establish a nonparametric estimate of the survival function, while Dinse [50] proposes nonparametric maximum likelihood estimators of prevalence and mortality. Dinse [51] and Kodell and Chen [52] considered bioassays for animal carcinogenicity where masking arises due to the disagreement on the reliability of the cause-of-death information. Several other authors also discuss the problem of missing cause-of-death in carcinogenicity studies [53,54]. Goetghebeur and Ryan [55] and Dewanji [56] construct a log-rank test to assess the difference between survival functions for subgroups of the population under study in the presence of covariates. Goetghebeur and Ryan [57] subsequently generalized the approach to proportional cause-specific hazards regression models. Lu and Tsiatis [58] utilized multiple imputations to generalize this to the case when the baselines are not proportional. Flehinger *et al.* [59,60] consider the analysis of datasets in which there are second stage data. They propose maximum likelihood estimation using a model with nonparametric proportional cause-specific hazards [59] and a model with completely parametric cause-specific hazards [60]. Dewanji and Sengupta [61] developed an Expectation-Maximization (EM) algorithm in the setting of masked but grouped survival data. Lu and Tsiatis [62] compared the two partial likelihood approaches in masked data. Basu *et al.* [63,64] developed Markov chain sampling based on Bayesian analysis for masked data.

Basu and Tiwari [48] considered analysis of unknown causes of death cases in breast cancer patients.

As noted before, the observed data in the absence of masking from n units or individuals are $\{t_i, c_i, i = 1, \dots, n\}$, where t_i is the time and c_i is the cause of event (with $c_i = 0$ denoting right-censoring). When some of the causes-of-events are masked, we instead represent the data as $\{t_i, s_i, i = 1, \dots, n\}$ where s_i denotes a set belonging to the power set of $\{1, \dots, R\}$ (i.e., s_i is a subset of $\{1, \dots, R\}$). For those units for which the cause of event is exactly identified as c_i , the set s_i is a singleton, that is, $s_i = \{c_i\}$. Right-censoring, as before, is denoted as $s_i = \{0\}$. When the cause is not exactly identified, s_i is not a singleton but is a subset of $\{1, \dots, R\}$ (such as $s_i = \{1, 2\}$), the cause is only narrowed down to belong to the set s_i . Guess *et al.* [65] first introduced the s_i notation.

When some of the causes are completely or partially masked, the likelihood of the observed data $\{t_i, s_i, i = 1, \dots, n\}$ can be written as

$$\prod_{i=1}^n \left[\sum_{c \in s_i} q(s_i | c, t_i) \left\{ (1-p) h(c, t_i | Q=0, \theta_{0,c})^{I(0 \notin s_i)} \exp \left(- \sum_{r=1}^R H(r, t_i | Q=0, \theta_{0,r}) \right) \right. \right. \\ \left. \left. I(c \neq 1) p h(c, t_i | Q=1, \theta_{1,c})^{I(0 \notin s_i)} \times \exp \left\{ - \sum_{r=2}^R H(r, t_i | Q=1, \theta_{1,r}) \right\} \right\} \right], \quad (6)$$

where we note that the only way $0 \in s_i$ is if $s_i = \{0\}$, that is, the event is right-censored. Further, the second term in the expression corresponds to the latent risk-free group and hence it does not appear when the failure is due to Risk 1.

The $q(s|c, t)$ in Equation (6) are the masking probabilities and are defined as

$$q(s|c, t) = P(\text{cause is masked in subset } s \mid \text{actual cause } C = c, T = t) \quad (7)$$

with $\sum_{s: c \in s} q(s|c, t) = 1$. If the masking probabilities $q(s|c, t)$ are constant in c , that

is, $q(s|c, t) = q(s|c', t)$ for all risks $c, c' \in$ the masking set s , then the $q(s|c, t)$ term can be ignored from the likelihood for likelihood-based inference. Guess *et al.* [65] described this as the “symmetry” condition, which, in some respect, is similar to the “missing at random” assumption in missing data literature. Similar symmetry condition is assumed in Schäbe’s [66] and Goetghebeur and Ryan [57] semiparametric formulations. Lin and Guess [67] and Gittman *et al.* [68] utilize a proportionality assumption to meet the symmetry condition.

For a unit whose cause-of-event is masked, a factor that is of interest concerns the actual cause of failure among those in the masking set s . This can be inferred based on the posterior probabilities or the diagnostic probabilities [59,69–73]

$$\pi(C = c|s, t) = P(\text{actual failure due to cause } c | \text{cause masked in } s, T = t), \quad (8)$$

which can be obtained from $q(s|c, t)$ and the likelihood model via Bayes rule. Flehinger *et al.* [59,60] consider an interesting case when further data are available from second-stage autopsy on a subset of masked units and propose maximum likelihood estimation using nonparametric proportional hazards [59] and completely parametric hazards [60]. Many authors Craiu and Duchesne [74], Craiu and Reiser [70], Mukhopadhyay [75], and Mukhopadhyay and Basu [76] assume that the masking probabilities are constant over time, that is, $q(s|c, t) = q(s|c)$ for all s, j , and t to achieve parsimony. Craiu and Reiser [70], Craiu and Lee [71], and Craiu and Duchesne [72] used EM-based methods, whereas Craiu and Duchesne [74] compared the performances of EM and Bayesian data augmentation methods in this scenario. Sen *et al.* [77] provided a recent review of competing risks analysis for masked data. Mukhopadhyay [75] obtained maximum likelihood estimation (MLE) and bootstrap estimates of these masking probabilities in a general setting and established consistency and asymptotic normality of the MLEs under suitable regularity conditions. Kuo and Yang [78] developed different models

for the masking probabilities and described Bayesian analysis of these models using Gibbs sampling methods. Mukhopadhyay [76] and Sen *et al.* [79] considered Bayesian models where the masking probabilities were assumed to have Dirichlet distribution prior and used Markov chain sampling for the posterior analysis.

EXAMPLE: COMPETING RISKS WITH LIMITED FAILURE AND MASKED CAUSES

We consider the setting of $R = 2$ competing risks, where a proportion p of the units are risk-free from the first risk and simulate $n = 100$ time-to-event observations. The cause-specific hazards for the two risks are taken to be Weibull with $h(r = 1, t|q = 0) = \lambda_1 \beta_1 t^{\beta_1 - 1}$ and $h(r = 2, t|q = 0) = h(r = 2, t|q = 1) = \lambda_2 \beta_2 t^{\beta_2 - 1}$, $t > 0$. Note that unless the β_j ’s are all equal, these hazards are nonproportional. The units fail at the earliest onset of the event due to either Risk 1 or Risk 2. Further, the causes of failure of a random sample of the units are randomly masked; their causes of failure are only recorded as the masking set $s = \{1, 2\}$. In actual simulation, we used $p = 0.25$ and 10 units had masked causes of failure. We considered a constant hazard (exponential) model for Risk 1 with $\lambda_1 = 0.005$ and $\beta_1 = 1$ and an increasing hazard rate for Risk 2 with $\lambda_2 = 0.0056$ and $\beta_2 = 1.5$. The parameters of the two hazards are matched to have similar median survival times.

In the model we fit, we assume that the cause-specific hazards have Weibull(λ_j, β_j) structure. The β_j ’s are allowed to be unequal, thus resulting in nonproportional hazards. The computations are actually performed in log-time scale as in Table 1, in the location-scale form of the Weibull (smallest extreme value) distribution. We assume independent flat normal prior on the location (μ) parameters and gamma priors on the τ parameters.

The results we report here are based on 20,000 iterations of the Markov chain sampler after a burn-in of 10,000 iterations. Table 2 shows the posterior mean of the risk-free fraction. We note that this estimate is

Figure 1. (a) The hazards in the data generating model (dark solid lines), the estimated (posterior mean) cause-specific hazards (solid lines) and 95% pointwise credible bands (dashed line). (b) The overall reliability/survival in the data generating model (dark solid line), the estimated (posterior mean) overall reliability/survival (solid line), and its 95% pointwise credible band.

Figure 2. Estimates of cumulative probabilities of failure from the two risks and the probability of survival.

Table 2. Estimate of the Risk-Free (from Risk 1) Fraction

Posterior Mean	95% Credible Interval
0.14	(0.005,0.395)

lower than the $p = 0.25$ of the data generating model. Estimation of the risk-free fraction is known to be a difficult problem [48] and the estimate is known to be sensitive to the modeling assumptions. The 95% credible interval shown in Table 2 does include $p = 0.25$ used in the data generation. Figure 1 plots the posterior means of the cause-specific hazards as well as the associated 95% pointwise credible bands. The constant and increasing shapes of the cause-specific hazards for Risks 1 and 2 in the data generating model are mostly captured by these estimates. The bottom panel shows the estimated overall reliability/survival curve estimate and its 95% credible band; these estimates are, in fact, quite accurate.

In Fig. 2, we show the estimates of the cumulative probability of failure from the two risks as well as the probability of non-failure/survival. The cumulative probability of failure from risk r at time t is defined as $P(C = r, T \leq t)$ whose expression includes evaluation of an integral. We estimate this integral numerically at each time-grid within each iteration of the Markov chain sampler. We note from Fig. 2 and Table 2 that while some units are risk-free from Risk 1, the chance of eventual failure (from either Risk 1 or Risk 2) is 1. This, in fact, is also seen in the overall reliability estimates in Fig. 1. We note from Fig. 2 that Risk 2 becomes the dominant risk because of its increasing hazard rate and because some of the units are risk-free from Risk 1.

In conclusion, we find that even in the presence of competing risks with some masked cause and limited failure from one risk, the overall reliability and cause-specific hazards could be estimated reasonable accurately in this limited study. The cure fraction estimate, however, is not so precise, but this is known to be a difficult estimation problem that is sensitive to modeling assumptions.

COMPLEMENTARITY PROBLEMS

IGOR V. KONNOV
Department of System Analysis
and Information Technologies,
Kazan University, Kazan,
Russia

BASIC DEFINITIONS

A set K in the n -dimensional Euclidean space $\mathbb{R}^n$ is said to be a cone if $\lambda K \subseteq K$ for any $\lambda \geq 0$. Let K be a convex cone in $\mathbb{R}^n$ and let $F: K \rightarrow \mathbb{R}^n$ be a mapping. Then, we can define the *complementarity problem* (CP for short)

$$\begin{aligned} x^* \in K, F(x^*) \in K^*, \langle x^*, F(x^*) \rangle \\ = \sum_{i=1}^n x_i^* F_i(x^*) = 0, \end{aligned} \quad (1)$$

where $K^* = \{z \in \mathbb{R}^n \mid \langle x, z \rangle \geq 0 \ \forall x \in K\}$ is the conjugate (dual) cone to K . There exist various subclasses and extensions of CP (1), but the following ones are those most investigated. The *standard complementarity problem* corresponds to the case where K is the nonnegative orthant $\mathbb{R}_+^n = \{x \in \mathbb{R}^n \mid x_i \geq 0, \ i = 1, \dots, n\}$, that is, the problem is to find

$$x^* \geq 0, F(x^*) \geq 0, \langle x^*, F(x^*) \rangle = 0 \quad (2)$$

or, equivalently,

$$\begin{aligned} x_i^* \geq 0, F_i(x^*) \geq 0, x_i^* F_i(x^*) = 0 \\ \text{for } i = 1, \dots, n. \end{aligned}$$

Here and in the subsequent discussions, all the inequalities for vectors are interpreted component-wise and 0 denotes the zero vector. Also, the *linear complementarity problem* (LCP) corresponds to the affine case where $F(x) = Ax - b$, A is an $n \times n$ matrix, and b is a fixed element in $\mathbb{R}^n$. Investigation of

CP (LCP) as a separate problem was initiated by the works of Dorn [1] and Cottle [2]; see also Harker and Pang [3], Cottle *et al.* [4], Isac [5], and Facchinei and Pang [6] for more details. CPs have a great number of direct applications in economics, mathematical physics, telecommunications, transportation, and other fields [3–5, 7–9]. For this reason, the theory and methods for CPs are investigated very extensively (see also the surveys by Billups and Murty [10] and Ferris and Kanzow [11] and edited books by Ferris and Pang [12], Fukushima and Qi [13], and Ferris *et al.* [14]). In this article, we intend to describe some of these results obtained by taking CP (2) as a basis. We also discuss their possible extensions.

THEORETICAL BACKGROUND

In this section, we consider CP (2) under the standing assumption that $F: \mathbb{R}_+^n \rightarrow \mathbb{R}^n$ is a continuous mapping. One of the general existence results from the theory of variational inequalities can be specialized for CP (2) as follows.

Theorem 1 [15,16]. *Suppose that there exists a nonempty bounded subset Y of $\mathbb{R}_+^n$ such that for every $x \in \mathbb{R}_+^n \setminus Y$ there is $y \in Y$ with $\langle F(x), x - y \rangle \geq 0$. Then CP (2) has a solution.*

Indeed, the set K in CPs is usually unbounded. Hence we cannot apply the Brouwer fixed point theorem directly [[17], Chapter I, Theorem 4.3] and have to utilize certain coercivity conditions such as that in Theorem 1. However, we can establish existence results by using the concept of the so-called exceptional family of elements.

Definition 1 [18]. A sequence $\{x^k\} \subset \mathbb{R}_+^n$ with $\|x^k\| = k$ is said to be an *exceptional family of elements* for a mapping F if the

following conditions are satisfied:

$$F_i(x^k) \begin{cases} = -\lambda_k x_i^k, & \text{if } x_i^k > 0, \\ \geq 0, & \text{if } x_i^k = 0, \end{cases} \quad \text{where } \lambda_k > 0.$$

Theorem 2 [18]. *If there is no exceptional family of elements for a mapping F , then CP (2) has a solution.*

It is easy to see that the coercivity condition in Theorem 1 implies the absence of an exceptional family of elements for the mapping F . Similarly, we can utilize some other sufficient coercivity conditions that are more suitable for their verification. Further development in this direction is found in Isac *et al.* [19].

We now recall some norm monotonicity concepts for mappings.

Definition 2. Let X be a convex set in $\mathbb{R}^n$. A mapping $Q : X \rightarrow \mathbb{R}^n$ is said to be

- (a) *monotone*, if for each pair of points $x, y \in X$, it holds that

$$\langle Q(x) - Q(y), x - y \rangle \geq 0;$$

- (b) *strictly monotone*, if for each pair of points $x, y \in X, x \neq y$, it holds that

$$\langle Q(x) - Q(y), x - y \rangle > 0;$$

- (c) *strongly monotone* with constant $\tau \geq 0$ if, for each pair of points $x, y \in X$, it holds that

$$\langle Q(x) - Q(y), x - y \rangle \geq \tau \|x - y\|^2.$$

Clearly, we have $(c) \implies (b) \implies (a)$. In the affine case $Q(x) = Ax - b$ is (strictly, strongly) monotone if and only if A is positive (definite) semidefinite matrix. In the differentiable case, the above monotonicity concepts are associated with the Jacobian properties [6, Proposition 2.3.2]. By the streamlined specialization of the known existence and uniqueness results from variational inequalities [9, Chapter 11], we can provide similar results for CP (2).

Proposition 1

- (i) *If F is strictly monotone, then CP (2) has at most one solution.*
- (ii) *If F is strongly monotone, then CP (2) has a unique solution.*

We now show that these results can be strengthened essentially in several directions.

Theorem 3

[20].

- (i) *If F is monotone and there exists a point $\bar{x} \geq 0$ such that $F(\bar{x}) > 0$, then CP (2) has a solution.*
- (ii) *If F is strictly monotone and there exists a point $\bar{x} \geq 0$ such that $F(\bar{x}) \geq 0$, then CP (2) has a unique solution.*

Next, we introduce several weaker concepts of order monotone mappings [5, 21–23].

Definition 3. Let X be a box constrained set in $\mathbb{R}_+^n$. A mapping $Q : X \rightarrow \mathbb{R}^n$ is said to be

- (a) a P_0 -mapping, if for each pair of points $x', x'' \in X, x' \neq x''$, there exists an index i such that $x'_i \neq x''_i$ and

$$(x'_i - x''_i) [Q_i(x') - Q_i(x'')] \geq 0;$$

- (b) a P -mapping, if for each pair of points $x', x'' \in X, x' \neq x''$, it holds that

$$\max_{1 \leq i \leq n} (x'_i - x''_i) [Q_i(x') - Q_i(x'')] > 0;$$

- (c) a *strict P -mapping*, if there exists $\varepsilon > 0$ such that $Q - \varepsilon I$ is a P -mapping.

Clearly, we have $(c) \implies (b) \implies (a)$. Also, it is obvious that each (strictly, strongly) monotone mapping is a (P -, strict P -) P_0 -mapping.

Definition 4. An $n \times n$ matrix A is said to be a P_0 - (P -) matrix, if it has nonnegative (positive) principal minors.

Note that in the affine case $Q(x) = Ax - b$ is a P_0 - (P -) mapping if and only if A is a P_0 - (P -) matrix.

matrix. However, $A = \begin{pmatrix} 2 & 5 \\ 0 & 2 \end{pmatrix}$ is clearly a P -matrix, but it is not even positive semidefinite. Nevertheless, these concepts coincide in the symmetric case, that is, each symmetric P_0 - (P -) matrix is a positive semidefinite (definite) matrix. In the differentiable case, we can utilize the corresponding properties of the Jacobian [4,17,21].

Theorem 4 [20,23,24].

- (i) If F is a P -mapping, then CP (2) has at most one solution.
- (ii) If F is a strict P -mapping, then CP (2) has a unique solution.

So, Theorem 4 strengthens Proposition 1.

Now, we turn to the results exploiting the Z -property (off-diagonal antitonicity) of the mapping F , which appears natural in many applications [4,5,25–29].

Definition 5. Let X be a box constrained set in $\mathbb{R}_+^n$. A mapping $Q : X \rightarrow \mathbb{R}^n$ is said to be

- (a) *isotone (antitone)*, if for each pair of points $x', x'' \in X$ such that $x' \geq x''$, it holds that $F(x') \geq F(x'')$ ($F(x') \leq F(x'')$);
- (b) a *Z -mapping* (or an *off-diagonal antitone mapping*), if, for each pair of points $x', x'' \in X$ such that $x' \geq x''$, it holds that $Q_k(x') \leq Q_k(x'')$ for each k such that $x'_k = x''_k$.

Again, in the affine case $Q(x) = Ax - b$ is an isotone (antitone, Z -) mapping if and only if A has only nonnegative entries (nonpositive entries, nonpositive off-diagonal entries, i.e., it is a Z -matrix). In the differentiable case, we can also utilize the corresponding properties of the Jacobian [4,21,22]. Let us define the auxiliary set

$$W = \{x \in \mathbb{R}^n \mid x \geq \mathbf{0}, F(x) \geq \mathbf{0}\}.$$

For each pair of points $x, y \in \mathbb{R}^n$, we can define their component-wise minimal point (meet) $z = \min\{x, y\}$ as follows:

$$z_i = \min\{x_i, y_i\} \quad \text{for } i = 1, \dots, n.$$

It appears $\min\{x, y\} \in W$ if $x, y \in W$, that is, W is a meet semisublattice if F is Z . Next, we can define the minimal element

$$\min W = \{z \in W \mid z \leq x \quad \forall x \in W\}.$$

One can now derive the special existence result; for more details refer to Yershov [28], Tamir [30], Cottle *et al.* [4], and Isac [5].

Theorem 5. If W is nonempty, $F : \mathbb{R}_+^n \rightarrow \mathbb{R}^n$ is a Z -mapping, then CP (2) has a solution, which coincides with $\min W$.

Note that CP (2) here may admit many solutions. However, additional assumptions, say from Theorem 4 provide uniqueness. Certain results above can be adjusted for CP (1) and further extended to infinite-dimensional spaces; for more details refer to Cottle *et al.* [3], Isac [5], Isac *et al.* [19], and Yao and Chadli [31].

RELATED PROBLEMS

It is known [32] that CP (1) is equivalent to the following *variational inequality* (VI): find $x^* \in K$ such that

$$\langle F(x^*), x - x^* \rangle \geq 0 \quad \forall x \in K. \quad (3)$$

Thus, CPs can in principle be viewed as special classes of VIs where the feasible set is a cone (or a cone segment). These features enable one to essentially enhance many results in the theory and solution methods for CPs in comparison with those for general VIs; see in particular, the section titled “Theoretical Background”. The above property enables one to establish relations of CPs with other general problems.

For instance, let T be a continuous mapping from K into itself. Then the *fixed point problem* which is to find a point $x^* \in K$ such that $x^* = T(x^*)$ coincides with VI (3), where

$$F(x) = x - T(x), \quad (4)$$

and hence with CP (1), (4) [33], [Section 3.1]. Moreover, if T is isotone, then F in Equation(4) is clearly a Z -mapping.

Let us now define the *optimization problem* of finding a point $x^* \in K$ such that

$$\varphi(x^*) \leq \varphi(x) \quad \forall x \in K,$$

or, briefly,

$$\min \rightarrow \{\varphi(x) \mid x \in K\} \quad (5)$$

and suppose that $\varphi : X \rightarrow \mathbb{R}$ is a differentiable function. Then Equation (5) implies VI (3) and CP (1) where $F(x) = \nabla \varphi(x)$, and the reverse implication holds if $\varphi : X \rightarrow \mathbb{R}$ is convex, that is, F is monotone. In this potential case, the Jacobian $\nabla F(x) = \varphi''(x)$ must be symmetric.

Let us consider the *constrained optimization problem*

$$\min \rightarrow \{\varphi_0(u) \mid u \in U\}, \quad (6)$$

where

$$U = \{u \in \mathbb{R}_+^l \mid \varphi_i(u) \leq 0 \quad i = 1, \dots, m\} \quad (7)$$

and $\varphi_i : \mathbb{R}^l \rightarrow \mathbb{R}$, $i = 0, \dots, m$ are convex differentiable functions. Set $n = l + m$ and define the mapping $F : \mathbb{R}^n \rightarrow \mathbb{R}^n$ as follows:

$$F(x) = F(u, v) = \begin{pmatrix} \nabla \varphi_0(u) + \sum_{i=1}^m v_i \nabla \varphi_i(u) \\ -\varphi(u) \end{pmatrix}, \quad (8)$$

where $\varphi(u) = (\varphi_1(u), \dots, \varphi_m(u))^T$. The relationships between problem (6)–(7) and CP (2), (8) are known as the *Karush–Kuhn–Tucker optimality conditions*. We need an additional constraint qualification. **(C)** *Either all the functions φ_i , $i = 1, \dots, m$ are affine, or there exists a point $\bar{u} \in \mathbb{R}_+^l$ such that $\varphi_i(\bar{u}) < 0$ for all $i = 1, \dots, m$.*

Proposition 2 [17, Chapter 1, Theorems 3.16 and 3.17.

- (i) *If $x^* = (u^*, v^*)$ solves CP (2), (8) then x^* is a solution to problem (6)–(7).*

- (ii) *If x^* is a solution to problem (6)–(7) and condition (C) holds, then there exists a point $v^* \in \mathbb{R}_+^m$ such that (u^*, v^*) solves CP (2), (8).*

Note that F in Equation (8) is monotone, but its Jacobian $\nabla F(x)$ cannot be symmetric. Also, CP (2), (8) is in fact equivalent to the saddle point problem of the Lagrange function associated with problem (6)–(7):

$$L(u, v) = \varphi_0(u) + \sum_{i=1}^m v_i \varphi_i(u).$$

This is the case for more general convex–concave bi-functions; hence CPs can be used for solving zero-sum two-person games and even noncooperative games; for more details refer to Cottle *et al.* [3], Isac [5], Ferris and Pang [8], Isac *et al.* [19], Facchinei and Pang [6], and Konnov [9].

ALGORITHMS

At first we consider the case of LCP when $F(x) = Ax - b$ in Equation (2). If the matrix A is arbitrary, even this problem can be too hard for a solution. However, if A is positive (semi)definite or possesses P -type properties, there exist a number of the so-called *pivotal algorithms*, which yield a solution in a finite number of iterations [4,34]. These algorithms, which include the most-known Lemke method [35], create a finite sequence of special systems of linear equations with pivotal exchanges of basic and nonbasic variables and maintenance of certain additional conditions. It may also be observed that the above LCP becomes equivalent to the convex quadratic programming problem

$$\min_{x \in \mathbb{R}_+^n} \rightarrow 0.5 \langle Ax, x \rangle - \langle b, x \rangle,$$

if A is symmetric and positive semidefinite. Let us now consider the general case of CP (2) where $F : \mathbb{R}_+^n \rightarrow \mathbb{R}^n$ is a continuous mapping. Observe that pivotal algorithms can be extended to this problem. They involve sequential solution of auxiliary nonlinear equations and require certain

order monotonicity properties [36,37]. However, the *linearization algorithms* based on the sequential solution of LCP problems constitute one of the most popular and investigated classes. At the k th iteration of such an algorithm, given a point $x^k \in \mathbb{R}_+^n$, the next iterate x^{k+1} is defined as a solution of the LCP:

$$x^{k+1} \geq 0, F^k(x^{k+1}) \geq 0, \langle x^{k+1}, F^k(x^{k+1}) \rangle = 0, \quad (9)$$

where $F^k(x) = F(x^k) + C_k(x - x^k)$, C_k is an $n \times n$ matrix. Different choice of C_k leads to various iterative methods. For instance, setting $C_k = \nabla F(x^k)$ ($C_k = 0.5(\nabla F(x^k) + \nabla F(x^k)^\top)$, respectively) gives the Newton (respectively, symmetric Newton) method, while setting $C_k = C$ with a symmetric and positive definite matrix C gives the projection method. Besides, one can take C_k as a part or an approximation of $\nabla F(x^k)$, thus obtaining in particular linearized Jacobi, successive overrelaxation, Levenberg–Marquardt, quasi-Newton methods, and so on. Concerning the convergence of the linearization algorithms we note that approximation of $\nabla F(x^k)$ usually yields rather rapid convergence which is however local, the Newton method attaining the highest quadratic convergence rate.

Theorem 6 [38], Corollary 2.6. *Suppose that x^* solves CP (2), F is continuously differentiable, and $\nabla F(x^*)$ is positive definite. Then, there exists a neighborhood U of x^* such that the sequence $\{x^k\}$ generated by the Newton method is well defined and converges to x^* if $x^0 \in U$. Moreover, if ∇F is Lipschitz continuous in a neighborhood U' of x^* , then $\{x^k\}$ converges quadratically to x^* , that is, there is a constant τ such that $\|x^{k+1} - x^*\| \leq \tau \|x^k - x^*\|^2$.*

Observe that the above positive definiteness of $\nabla F(x^*)$ can be replaced by a weaker regularity condition. The known drawback of the Newton type methods is their very restrictive assumptions for providing global convergence. The simplest projection

method corresponds to Equation (9) with $F^k(x) = F(x^k) + \lambda_k^{-1}I(x - x^k)$ where I is an $n \times n$ unit matrix and $\lambda_k > 0$ and is equivalent to the iterate $x^{k+1} = [x^k - \lambda_k F(x^k)]_+$, where $[a]_+$ denotes the projection of a onto $\mathbb{R}_+^n$. Its global convergence also requires strengthened monotonicity properties and knowledge of the corresponding constants. By utilizing suitable extrapolation procedures, one can provide convergence without such restrictive assumptions [39,40].

Another approach consists in replacing the initial CP (2) by an optimization problem via introduction of some artificial *merit function*, which admits algorithms with line search procedures. For instance, the regularized merit function suggested by Fukushima [41] is defined as follows:

$$\begin{aligned} \varphi_\lambda(x) &= \max_{y \in \mathbb{R}_+^n} \left\{ \langle F(x), x - y \rangle - (2\lambda)^{-1} \|x - y\|^2 \right\} \\ &= \langle F(x), x \rangle + (2\lambda)^{-1} \left\{ \|x - \lambda F(x)\|_+^2 - \|x\|^2 \right\}, \quad \lambda > 0. \end{aligned}$$

Let CP (2) be solvable. Then φ_λ is nonnegative on $\mathbb{R}_+^n$ and attains its minimal (zero) value, that is, CP (2) becomes equivalent to

$$\min_{x \in \mathbb{R}_+^n} \varphi_\lambda(x). \quad (10)$$

Moreover, if $\nabla F(x)$ is a P -matrix for all $x \geq 0$, then the CP

$$x^* \geq 0, \quad \nabla \varphi_\lambda(x^*) \geq 0, \quad \langle \nabla \varphi_\lambda(x^*), x^* \rangle = 0$$

becomes equivalent to both CP (2) and the optimization problem (10). Therefore, one can apply any gradient descent algorithm to Equation (10) in order to find a solution for CP (2). In addition, if $\nabla F(x)$ is a positive definite matrix for all $x \geq 0$, then one can apply the descent algorithms with line search with respect to φ_λ , where solutions of the auxiliary problem (9) are used for computing the descent direction at x^k , including Newton and projection iterates [6,9,42].

There exist a number of merit functions, which can possess some additional nice properties. It is possible to define a merit function

ψ on the whole space, that is, ψ is nonnegative on $\mathbb{R}^n$ and attains its minimal (zero) value; hence CP (2) becomes equivalent to the unconstrained optimization problem

$$\min_{x \in \mathbb{R}^n} \psi(x). \quad (11)$$

For instance, the so-called implicit Lagrangian [43]

$$\psi_{\text{MS}}(x) = \langle F(x), x \rangle + (2\lambda)^{-1} \left(\| [x - \lambda F(x)]_+ \|^2 - \|x\|^2 + \| [F(x) - \lambda x]_+ \|^2 - \|F(x)\|^2 \right),$$

where $\lambda > 1$ meets these conditions. Observe that $\psi_{\text{MS}}(x) = \varphi_\lambda(x) - \varphi_{1/\lambda}(x)$, that is, it coincides with the so-called *D-gap function* [6,42,44]. Most of such functions of ψ can be created within the *equation reduction approach*. In fact, let a function $\phi : \mathbb{R}^2 \rightarrow \mathbb{R}$ satisfy the conditions

$$\phi(\alpha, \beta) = 0 \implies \alpha \geq 0, \beta \geq 0, \alpha\beta = 0.$$

Then, ϕ is called an *NCP-function*. If one defines the mapping $\Psi : \mathbb{R}^n \rightarrow \mathbb{R}^n$ by $\Psi_i(x) = \phi(x_i, F_i(x))$ for $i = 1, \dots, n$, then CP (2) becomes equivalent to the nonlinear equation

$$\Psi(x^*) = \mathbf{0}, \quad (12)$$

and, also to problem (11) where

$$\psi(x) = 0.5 \|\Psi(x)\|^2.$$

Clearly, $\psi_{\text{MS}}(x)$ corresponds here to

$$\phi_{\text{MS}}(\alpha, \beta) = \alpha\beta + (2\lambda)^{-1} \left\{ [\alpha - \lambda\beta]_+^2 - \alpha^2 + [\beta - \lambda\alpha]_+^2 - \beta^2 \right\}$$

with $[\gamma]_+ = \max\{\gamma, 0\}$. Besides, one can take

- (i) the min function [3] $\phi_{\min}(\alpha, \beta) = \min\{\alpha, \beta\}$,
- (ii) the Fischer–Burmeister function [45] $\phi_{\text{FB}}(\alpha, \beta) = \sqrt{\alpha^2 + \beta^2} - \alpha - \beta$, and many others [6].

Despite the possible nonsmoothness of the mapping Ψ , Newton type methods can also be used to find a solution to Equation (12) (or Equation (2)). Namely, the next iterate x^{k+1} is defined as a solution of the equation

$$F(x^k) + H_k(x - x^k) = \mathbf{0},$$

where H_k is an analog (or approximation) of the Jacobian, for instance, an element of the Clarke generalized Jacobian $\partial^\uparrow F(x^k)$ [46]. Similarly, a line search procedure with respect to ψ is used to provide global convergence for these methods. Nevertheless, computation of the matrix H_k can meet certain difficulties in the nonsmooth case, whereas smooth mappings Ψ usually have singular Jacobian matrices at degenerate solutions (i.e., when there exists an index k such that both $x_k^* = 0$ and $F_k(x^*) = 0$ at a solution x^*), which prevents the direct application of the Newton method and leads to slow convergence. In order to overcome these difficulties, one can utilize the *continuation approach*, which yields in particular, smooth approximate mappings. Following this approach, one replaces CP (2) by a parameterized problem of the form

$$\begin{aligned} x_i(\mu) &\geq 0, F_i(x(\mu)) \geq 0, x_i(\mu)F_i(x(\mu)) = \mu \\ \text{for } i &= 1, \dots, n, \end{aligned} \quad (13)$$

where $\mu > 0$. Under certain regularity assumptions, it is possible to show that the trajectory $x(\mu)$ will approximate a solution x^* as $\mu \rightarrow 0$. At the same time, this idea can be implemented via replacing ϕ (or Ψ) with its smooth approximation. For instance, utilizing the smoothing Fischer–Burmeister function $\phi_{\text{FB}}^\mu(\alpha, \beta) = \sqrt{\alpha^2 + \beta^2 + \mu} - \alpha - \beta$, one can define the approximate mapping Ψ^μ by $\Psi_i^\mu(x) = \phi_{\text{FB}}^\mu(x_i, F_i(x))$ for $i = 1, \dots, n$, which is smooth if F is so, and then replace Equation (12) by

$$\Psi^\mu(z(\mu)) = \mathbf{0}.$$

Note that $z(\mu)$ satisfies Equation (13), and moreover, $z_i(\mu) > 0$ and $F_i(z(\mu)) > 0$ for $i = 1, \dots, n$. Therefore, it is also treated as an *interior point method* where the solutions $z(\mu)$ form the so-called central path. In order to

solve CP (2), one can thus solve Equation (12) within a given accuracy ε by the suitable Newton method

$$\Psi^\mu(x^k) + \nabla \Psi^\mu(x^k)(x^{k+1} - x^k) = \mathbf{0},$$

(with inserting line search with respect to $\psi^\mu(x) = 0.5\|\Psi^\mu(x)\|^2$ if necessary) and drive μ and ε to 0. The single-level scheme

$$\Psi^{\mu_k}(x^k) + \nabla \Psi^{\mu_k}(x^k)(x^{k+1} - x^k) = \mathbf{0},$$

with simultaneous changes in x^k and $\mu_k \rightarrow 0$ may even appear more efficient here. Within this approach there exist a great number of algorithms, basic and smoothing functions [6,12,13]. Now we turn to the methods that are based on exploiting the Z -property of the mapping F . As discussed above, features of Z -mappings enable us to suggest efficient tools for finding a solution for CP (2). In fact, the nonlinear *coordinate relaxation* (e.g., Jacobi and Gauss–Seidel) algorithms can be then applied to find solutions [4,5,20,21,30,38]. Now, we present a splitting algorithm that utilizes a Jacobi type iteration. It follows Konnov [47] and simplifies similar algorithms of Pang and Chan [38] and Konnov [48].

Let us consider CP (2) where

$$F(x) = G(x) + H(x),$$

$G : \mathbb{R}_+^n \rightarrow \mathbb{R}^n$ is a continuous Z -mapping, and $H : \mathbb{R}_+^n \rightarrow \mathbb{R}^n$ is a continuous antitone mapping.

Algorithm (JS). Choose a point $x^0 \in W$. At the k th iteration, $k = 0, 1, \dots$, we have a point $x^k \in W$. For each separate index $i = 1, \dots, n$, we determine a number x_i^{k+1} as follows: if $G_i(x_{-i}^k, 0) + H_i(x^k) \geq 0$, then set $x_i^{k+1} = 0$; otherwise find $x_i^{k+1} \in [0, x_i^k]$ such that $G_i(x_{-i}^k, x_i^{k+1}) + H_i(x^k) = 0$.

Theorem 7. Suppose that W is nonempty. Then Algorithm (JS) is well defined and generates a sequence $\{x^k\}$ converging to a solution x^* of CP (2).

The Jacobi basic iteration can be replaced by the Gauss–Seidel iteration with similar convergence properties.

Most existence and uniqueness results and convergence properties for solution methods are guaranteed under strengthened (order) monotonicity properties. If they are too restrictive, certain *regularization* techniques can be applied. For instance, the classical Tikhonov–Browder regularization leads to the following auxiliary problem:

$$x^\varepsilon \geq \mathbf{0}, F(x^\varepsilon) + \varepsilon x^\varepsilon \geq \mathbf{0}, \langle F(x^\varepsilon) + \varepsilon x^\varepsilon, x^\varepsilon \rangle = 0, \quad (14)$$

where $\varepsilon > 0$. In the case when F is monotone and continuous, it is known [49] that each problem (14) has a unique solution and that the sequence of solutions $\{x^\varepsilon\}$ converges to the minimal norm solution x_n^* of CP (2) as $\varepsilon \rightarrow 0$. Note that the cost mapping $F^\varepsilon = F + \varepsilon I$ in Equation (14) is then strongly monotone. The problem is to maintain at least some part of these nice convergence properties in the case when F is order monotone, say, satisfies the P_0 condition. Then, F^ε is strict P and each problem (14) has a unique solution [4,24,50]. However, even weakened convergence properties of regularization schemes will require certain additional conditions. For instance, this is the case if the solution set of CP (2) is nonempty and bounded [6,24]. Another approach to justifying regularization methods for nonmonotone CPs consists in utilizing coercivity conditions [51,52]. For instance, if the assumptions of Theorem 1 are fulfilled, then each CP (14) has a solution, each sequence $\{x^\varepsilon\}$ has limit points, and if $\{\varepsilon_k\} \searrow 0$ all these limit points are solutions of CP (2) [52,53]. The proximal point method [54,55] also consists in replacing the initial problem with a sequence of auxiliary ones, but its regularization parameter may be in principle fixed and the perturbed mapping depends on the previous iteration point. At the same time, its convergence requires certain (generalized) monotonicity properties [56,57].

EXTENSIONS

Now we turn to some extensions. For instance, replacing the nonnegativity of

variables in Equation (2) with the two-sided constraints or allowing for possible unrestricted variables, we obtain the *mixed complementarity problem* (MCP): Find $x^* \in D$ such that

$$F_i(x^*) \begin{cases} \geq 0 & \text{if } x_i^* = a_i, \\ = 0 & \text{if } x_i^* \in (a_i, b_i), \\ \leq 0 & \text{if } x_i^* = b_i, \end{cases} \quad \text{for } i = 1, \dots, n, \quad (15)$$

where

$$D = \{x \in \mathbb{R}^n \mid -\infty \leq a_i \leq x_i \leq b_i \leq +\infty \\ i = 1, \dots, n\} \quad (16)$$

is a box-constrained (rectangle) set or a cone segment with respect to the ordering defined by $\mathbb{R}_+^n$. Similarly, we can utilize cone segment restrictions in CP (1) instead of the cone K and obtain its extension. Again, MCP (15)–(16) is also equivalent to VI: Find $x^* \in D$ such that

$$\langle F(x^*), x - x^* \rangle \geq 0 \quad \forall x \in D, \quad (17)$$

compare Equation (3). We note that the previous results obtained for CP (2) can be extended to this box-constrained VI (17) (or to MCP (15)–(16)) after proper modifications [3,8,6,9,29,53,57].

Further extensions may consist in replacing the single-valued cost mapping with the multivalued mapping. So, let K be a convex cone in $\mathbb{R}^n$ and let $\mathbf{F} : K \rightarrow \Pi(\mathbb{R}^n)$ be a multivalued mapping, where $\Pi(S)$ denotes the family of all subsets of a set S . Then, we can define the *generalized complementarity problem* (GCP):

$$x^* \in K, \exists f^* \in \mathbf{F}(x^*), f^* \in K^*, \langle f^*, x^* \rangle = 0, \quad (18)$$

compare Equation (1). In case $K = \mathbb{R}_+^n$, Equation (18) reduces to the standard GCP:

$$x^* \geq 0, \exists f^* \in \mathbf{F}(x^*), f^* \geq 0, \langle f^*, x^* \rangle = 0, \quad (19)$$

compare (2). In turn, GCP (18) is equivalent to the *generalized variational inequality*

problem (GVI), which is to find an element $x^* \in K$ such that

$$\exists f^* \in \mathbf{F}(x^*), \langle f^*, y - x^* \rangle \geq 0 \quad \forall y \in K, \quad (20)$$

so that GCP (19) coincides with GVI (20) where $K = \mathbb{R}_+^n$. The multivalued extensions of the box-constrained VI (17) and MCP (15)–(16) are defined similarly. The necessity to investigate and solve such problems stems from the fact that many applied models with complementarity conditions involve just multivalued mappings [5,8,17,26,29,40,50,52].

The basic existence and uniqueness results from the section titled “Theoretical Background” contained in Theorems 1 and 2 are transformed directly for GCP (19). This is the case for the norm monotonicity and P -type assumptions after their proper extensions [5,23,40,50,52]. However, the streamlined extension of the Z -mapping concept meets certain difficulties and analogs of Theorem 5 are established for some subclasses of multivalued mappings [29,58]. In view of the equivalence results, iterative solution methods devised for GVI (20) are applicable for GCPs (18) and (19) [40,59]. We also notice that the results described in the section titled “Algorithms” for the regularization and proximal point methods remain true in the multivalued case [52,57]. Again, after proper modifications the splitting and coordinate relaxation (e.g., Jacobi and Gauss–Seidel) algorithms can be applied to GCP (19), but their convergence is established for some subclasses of multivalued Z -type mappings [29,47,48,58,60,61]. In addition, we observe that the D -gap function approach enables one to convert GCP (19) whose cost mapping is the sum of a monotone (or P -type) single-valued differentiable mapping and a multivalued diagonal monotone mapping into an unconstrained differentiable optimization problem and to develop efficient descent methods [62,23].

COMPUTATION AND DYNAMIC PROGRAMMING

HUSEYIN TOPALOGLU
School of Operations Research and
Information Engineering, Cornell
University, Ithaca, New York

Dynamic programming is a powerful tool for solving sequential decision-making problems that take place under uncertainty. One appeal of dynamic programming is that it provides a structured approach for computing the value function, which assesses the cost implications of being in different states. The value function can ultimately be used to construct an optimal policy to control the evolution of the system over time. However, the practical use of dynamic programming as a computational tool has traditionally been limited. In many applications, the number of possible states can be so large that it becomes intractable to compute the value function for every possible value of the state. This is especially the case when the state is itself a high dimensional vector and the number of possible values for the state grows exponentially with the number of dimensions of the vector. This difficulty is compounded by the fact that computing the value function requires taking expectations and it may be difficult to estimate or store the transition probability matrices that are involved in these expectations. Finally, we need to solve optimization problems to find the best action to take in each state and these optimization problems can be intractable when the number of possible actions is large.

In this article, we give an overview of computational dynamic programming approaches that are directed toward addressing the difficulties described above. Our presentation begins with the value and policy iteration algorithms. These algorithms are perhaps the most standard approaches for solving dynamic programs and they provide a sound starting point for the subsequent development, but they quickly

lose their tractability when the number of states or actions is large. Following these standard approaches, we turn our attention to simulation-based methods, such as the temporal difference learning and Q-learning algorithms, that avoid dealing with transition probability matrices explicitly when computing expectations. We cover variants of these methods that alleviate the difficulty associated with storing the value function by using parameterized approximation architectures. The idea behind these variants is to use a succinctly parameterized representation of the value function and tune the parameters of this representation by using simulated trajectories of the system. Another approach for approximating the value function is based on solving a large linear program to tune the parameters of a parameterized approximation architecture. The appealing aspect of the linear programming approach is that it naturally provides a lower bound on the value function. There are methods that use a combination of regression and simulation to construct value function approximations. In particular, we cover the approximate policy iteration algorithm that uses regression in conjunction with simulated cost trajectories of the system to estimate the discounted cost incurred by a policy. Following this, we describe rollout policies that build on an arbitrary policy and improve the performance of this policy with reasonable amount of work. Finally, we cover state aggregation, which deals with the large number of states by partitioning them into a number of subsets and assuming that the value function takes a constant value over each subset. Given the introductory nature of this article and the limited space, our coverage of computational dynamic programming approaches is not exhaustive. In our conclusions, we point out other approaches and extensions, such as linear and piecewise linear value function approximations and Lagrangian relaxation-based decomposition methods.

There are excellent books on approximate dynamic programming that focus on

computational aspects of dynamic programming. Bertsekas and Tsitsiklis [1] lay out the connections of dynamic programming with the stochastic approximation theory. They give convergence results for some computational dynamic programming methods by viewing these methods as stochastic approximation algorithms. Sutton and Barto [2] provide a perspective from the computer science angle and document a large body of work done by the authors on reinforcement learning. Si *et al.* [3] cover computational dynamic programming methods with significant emphasis on applications from a variety of engineering disciplines. Powell [4] focuses on dynamic programs where the state and the action are high dimensional vectors. Such dynamic programs pose major challenges as one can neither enumerate over all possible values of the state to compute the value function nor enumerate overall possible actions to decide which action to take. The author presents methods that can use mathematical programming tools to decide which action to take and introduces a post decision state variable that cleverly bypasses the necessity to compute expectations explicitly. The development in Powell [4] is unique in the sense that it simultaneously addresses the computational difficulties associated with the number of states, the number of actions, and the necessity to compute expectations. Bertsekas [5] provides a variety of computational dynamic programming tools. The tools in that book chapter deal with the size of the state space by using parameterized representations of the value function and avoid computing expectations by using simulated trajectories of the system. Many value function approximation approaches are rooted in standard stochastic approximation methods. Comprehensive overviews of the stochastic approximation theory can be found in Bertsekas and Tsitsiklis [1], Kushner and Clark [6], Benveniste *et al.* [7], and Kushner and Yin [8]. In this paragraph, we have broadly reviewed the literature on computational dynamic programming and value function approximation methods, but throughout the article, we point to the

relevant literature in detail at the end of each section.

The rest of the article is organized as follows. In the section titled “Notation and Problem Setup,” we formulate a Markov decision problem, give a characterization of the optimal policy, and briefly describe the value and policy iteration algorithms for computing the optimal policy. In the section titled “Policy Evaluation with Monte Carlo Simulation,” we give simulation-based approaches for computing the discounted cost incurred by a policy. We describe a simple procedure for iteratively updating an approximation to the discounted cost. This updating procedure is based on a standard stochastic approximation iteration and we use the updating procedure to motivate and describe the temporal difference learning method. In the section titled “Model-Free Learning,” we cover the Q-learning algorithm. An important feature of the Q-learning algorithm is that it avoids dealing with the transition probability matrices when deciding which action to take. This feature becomes useful when we do not have a precise model of the system that describes how the states visited by the system evolve over time. In the section titled “Linear Programming Approach,” we demonstrate how we can use a large scale linear program to fit an approximation to the value function. This linear program often has too many constraints to be solved directly and we describe computational methods to solve the linear program. In the section titled “Approximate Policy Iteration,” we describe an approximate version of the policy iteration algorithm that uses regression to estimate the discounted cost incurred by a policy. In the section titled “Rollout Policies,” we explain rollout policies and show that a rollout policy always improves the performance of the policy from which it is derived. In the section titled “State Aggregation,” we show how to use state aggregation to partition the set of states into a number of subsets and assume that the value function is constant over each subset. In the section titled “Conclusions,” we conclude by describing some other methods and possible extensions that can further enhance the computational appeal of dynamic programming.

NOTATION AND PROBLEM SETUP

In this article, we are interested in infinite horizon, discounted cost Markov decision problems with finite sets of states and actions, which we respectively denote by $\mathcal{S}$ and $\mathcal{U}$. If the system is in state i and we use action u , then the system moves to state j with probability $p_{ij}(u)$ and we incur a cost of $g(i, u, j)$, where $|g(i, u, j)| < \infty$. The costs in the future time periods are discounted by a factor $\alpha \in [0, 1)$ per time period. We use $\mathcal{U}(i)$ to denote the set of admissible actions when the system is in state i . We assume that $\mathcal{S} = \{1, 2, \dots, n\}$ so that there are n states. For brevity, we restrict our attention to infinite horizon, discounted cost Markov decision problems, but it is possible to extend the algorithms in this article to finite horizon problems or average cost criterion.

A Markovian deterministic policy π is a mapping from $\mathcal{S}$ to $\mathcal{U}$ that describes which action to take for each possible state. As a result, the states visited by the system under policy π evolve according to a Markov chain with the transition probability matrix $P^\pi = \{p_{ij}(\pi(i)) : i, j \in \mathcal{S}\}$. Letting $\{i_0^\pi, i_1^\pi, \dots\}$ be the states visited by this Markov chain, if we start in state i and use policy π , then the discounted cost that we incur can be written as

$$\begin{aligned} J^\pi(i) &= \lim_{T \rightarrow \infty} \mathbb{E} \left\{ \sum_{t=0}^T \alpha^t g(i_t^\pi, \pi(i_t^\pi), i_{t+1}^\pi) \mid i_0^\pi = i \right\}. \end{aligned}$$

Using Π to denote the set of Markovian deterministic policies, the optimal policy π^* satisfies $J^{\pi^*}(i) = \min_{\pi \in \Pi} J^\pi(i)$ for all $i \in \mathcal{S}$, giving the minimum discounted cost starting from each state. This policy can be obtained by solving the optimality equation

$$J(i) = \min_{u \in \mathcal{U}(i)} \left\{ \sum_{j \in \mathcal{S}} p_{ij}(u) [g(i, u, j) + \alpha J(j)] \right\} \quad (1)$$

for $\{J(i) : i \in \mathcal{S}\}$ and letting $\pi^*(i)$ be the optimal solution to the optimization problem on the right side above. If we let $J^* = \{J^*(i) : i \in \mathcal{S}\}$ be a solution to the optimality equation (1), then $J^*(i)$ corresponds to the optimal

discounted cost when we start in state i . We refer to $J^* \in \mathbb{R}^n$ as the “value function” and J^* can be interpreted as a mapping from $\mathcal{S}$ to $\mathbb{R}$, giving the optimal discounted cost when we start in a particular state.

The optimality equation (1) characterizes the optimal policy, but it does not provide an algorithmic tool for actually computing the optimal policy. We turn our attention to standard algorithmic tools that can be used to solve the optimality equation (1).

Value Iteration Algorithm

Throughout the rest of this article, it is useful to interpret the value function J^* not only as a mapping from $\mathcal{S}$ to $\mathbb{R}$, but also as an n dimensional vector whose i th component $J^*(i)$ gives the optimal discounted cost when we start in state i . For $J \in \mathbb{R}^n$, we define the nonlinear operator T on $\mathbb{R}^n$ as

$$[TJ](i) = \min_{u \in \mathcal{U}(i)} \left\{ \sum_{j \in \mathcal{S}} p_{ij}(u) [g(i, u, j) + \alpha J(j)] \right\}, \quad (2)$$

where $[TJ](i)$ denotes the i th component of the vector TJ . In this case, the optimality equation (1) can succinctly be written as $J = TJ$ and the value function J^* is a fixed point of the operator T . The idea behind the value iteration algorithm is to find a fixed point of the operator T by starting from an initial vector $J^1 \in \mathbb{R}^n$ and successively applying the operator T . In particular, the value iteration algorithm generates a sequence of vectors $\{J^k\}_k$ with $J^{k+1} = TJ^k$.
